Description**PRIORITY DATA**

5 [0001] This application claims the benefit of U.S. Provisional Application No. 61/393,747, filed October 15, 2010.

BACKGROUND

10 [0002] A seizure may be characterized as abnormal or excessive synchronous activity in the brain. At the beginning of a seizure, neurons in the brain may begin to fire at a particular location. As the seizure progresses, this firing of neurons may spread across the brain, and in some cases, many areas of the brain may become engulfed in this activity. Seizure activity in the brain may cause the brain to send electrical signals through the peripheral nervous system to different muscles. For example, an electrical signal may originate in the central nervous system and initiate the propagation of an electrical signal through motor neurons. A motor neuron may, for example, communicate with a muscle through interaction with the motor end plate of a muscle fiber; thereby initiating an action potential and depolarization of muscle cells within a given motor unit. Depolarization typically results from the coordinated flow of ions, e.g., sodium and potassium cations, through channels within a muscle cell membrane. That is, changes in states of ion channels initiate a change in the permeability of a cell membrane, and subsequent redistribution of charged ions. Current flow through muscle cells may initiate a corresponding flow in the tissue above the muscle and thus an electrical signature at the surface of the skin.

20 [0003] Techniques designed for studying and monitoring seizures have typically relied upon electroencephalography (EEG), which characterizes electrical signals using electrodes attached to the scalp or head region of a seizure prone individual, or seizure patient. EEG electrodes may be positioned so as to measure such activity, that is, electrical activity originating from neuronal tissue. Compared to EEG, electromyography (EMG) is a little-used technique in which an electrode may be placed on or near the skin, over a muscle, to detect an electrical current or change in electric potential in response to redistribution of ions within muscle fibers.

25 [0004] Detecting an epileptic seizure using electroencephalography (EEG) typically requires attaching many electrodes and associated wires to the head and using amplifiers to monitor brainwave activity. The multiple EEG electrodes may be very cumbersome and generally require some technical expertise to apply and monitor. Furthermore, confirming a seizure requires observation in an environment provided with video monitors and video recording equipment. Unless used in a staffed clinical environment, such equipment is frequently not intended to determine if a seizure is in progress but rather provide a historical record of the seizure after the incident. Such equipment is usually meant for hospital-like environments where a video camera recording or caregiver's observation may provide corroboration of the seizure, and is typically used as part of a more intensive care regimen such as a hospital stay for patients who experience multiple seizures. A hospital stay may be required for diagnostic purposes or to stabilize a patient until suitable medication can be administered. Upon discharge from the hospital, a patient may be sent home with little further monitoring. However, at any time after being sent home the person may experience another seizure, perhaps fatal.

35 [0005] A patient should in some cases be monitored at home for some length of time in case another seizure should occur. Seizures with motor manifestations may have patterns of muscle activity that include rhythmic contractions of some, most, or all of the muscles of the body. A seizure could, for example, result in Sudden Unexplained Death in Epilepsy (SUDEP). The underlying causes of SUDEP are not well understood; however, some possible mechanisms causing SUDEP may include tonic activation of the diaphragm muscle so as to prevent breathing, neurogenic pulmonary edema, asystole, and other cardiac dysrhythmia. If a sleeping person experiences a seizure involving those conditions, then caregivers may not be aware that the seizure is occurring, and thus be unable to render timely aid.

40 [0006] While there presently exist ambulatory devices for diagnosis of seizures, they are EEG-based and are generally not designed or suitable for long-term home use or daily wearability. Other seizure alerting systems may operate by detecting motion of the body, usually the extremities. Such systems may generally operate on the assumption that while suffering a seizure, a person will move erratically and violently. For example, accelerometers may be used to detect violent extremity movements. However, depending upon the type of seizure, this assumption may or may not be true. Electrical signals sent from the brain during the seizure are frequently transmitted to many muscles simultaneously, which may result in muscles fighting each other and effectively canceling out violent movement. In other words, the muscles may work to make the person rigid rather than cause actual violent movement. Thus, the seizure may not be consistently detected with accelerometer-based detectors.

45 [0007] Accordingly, there is a need for an epileptic seizure method and apparatus that can be used in a non-institutional or institutional environment without many of the cumbersome electrodes to the head or extremities. Such an apparatus may be minimally intrusive, minimally interfere with daily activities and be comfortably used while sleeping. There is also a need for an epileptic seizure method and apparatus that accurately detects a seizure with motor manifestations and may alert one or more local and/or remote sites of the presence of a seizure. Furthermore, there is a need for an epileptic

detection seizure method and apparatus that may be used in a home setting and which may provide robust seizure detection, even in the absence of violent motion, and which may be personalizable, e.g., capable of being tailored for an individual or specific population demographic.

5 [0008] WO 2008/31782 discloses an apparatus and a method for monitoring muscle activity. The apparatus comprises a sensor for detecting the generated electromyographic signals and processing means. The processing means generates an event signal if the electromyographic signal exceeds a predetermined power content within a predetermined time window. The event signal triggers an event, which may be an alarm. The apparatus further comprises communication means for transmitting the detected electromyographic signals from the sensor to the processing means. The method comprises the steps of detecting and evaluating the electromyographic signals. Furthermore, the method comprises
10 generating an event signal and triggering an event by the event signal.

SUMMARY

15 [0009] According to the invention, there is provided an apparatus for detecting seizures with motor manifestations according to claim. The invention is described in particular in par. [0107]-[0116] and par.[0122]-[0127].

[0010] Detecting seizures may comprise receiving an EMG signal and processing the received EMG signal to determine whether a seizure characteristic is present in the EMG signal during a time window.

20 [0011] In some examples, apparatuses and methods comprise a detection unit which includes EMG electrodes and a base unit in communication and physically separated from said detection unit, wherein the base station is configured for receiving and processing EMG signals from the detection unit, determining from the processed EMG signals whether a seizure may have occurred, and sending an alert to at least one caregiver. In some embodiments, the base station may separately process the data provided by the detection unit for verification of the alarm condition. If the base station agrees with the alarm, then the base station may generate an alarm to remote devices and local sound generators. Having the base station agree to the detection unit's alarm may introduce a voting concept. Both devices must vote on
25 the decision and agree to sound the alarm. This may be used to limit false alarms.

[0012] In some examples, a method and apparatus for detecting a seizure and providing a remote warning of that incident is provided. Such a method may detect seizures using EMG electrodes. One or more EMG electrodes may be attached to an individual's body and one or more characteristics from the signal output of the one or more EMG electrodes may be analyzed. EMG output may be compared to general seizure characteristics and to one or more threshold values.
30 If one or more values of the output data exceed one or more thresholds an event may be registered, e.g., logged on a register. Analysis of events logged in registers for different characteristics of the output data may be used to assess whether a seizure incident is declared and whether an alarm is sent to one or more locations.

[0013] In some examples, an apparatus for detecting seizures with motor manifestations may include a detector unit and a base unit. The detector unit may include one or more electromyography (EMG) electrodes, and optionally one or more electrocardiography (ECG) electrodes. The detector unit and base unit may be in communication with each other, such as by wireless communication. The detector unit and base unit may include electronic components configured to execute instructions for evaluation of EMG signal data. The base unit may be enabled for sending an alarm to one or more remote locations. Alternatively, the base unit may be in communication with a separate transceiver. That transceiver may be physically distinct but within the general locale of the base unit. That transceiver may be enabled for sending
40 an alarm to one or more remote locations.

[0014] In some examples, an alarm protocol may be initiated based on a convolution of data in a plurality of data registers. Individual registers may, for example, each be responsive to detection of a different seizure variable. An alarm protocol may be initiated if a supervisory algorithm, that supervisory algorithm responsive to the values in the plurality of registers, determines that an alarm protocol should be initiated.

45 [0015] In some examples, seizure detection methods as described herein may be adaptive. For example, threshold values may be adjusted as seizure data is collected from one or more patients. In addition, algorithms, which may be used to determine whether a seizure incident is declared, may be modified. Algorithms may, for example, be modified by adjusting variable coefficients. Those coefficients may be associated with, and weight, seizure variables. The adjustment of such coefficients may be based on seizure data that is collected from one or more patients, including, but not limited to an individual patient, or other patients, such as those of a particular demographic. The association between registered events, the initiation of alarm protocols, and seizure related incidents, e.g., declared events, actual seizures and inaccurately reported incidents, may be tracked and used to update variables in a detection method and thus improve the accuracy of a seizure detection method or apparatus.

50 [0016] In some examples, a historical record of patient seizure data and related incidents may be collected. A user may analyze a historical record and modify or change one or more sub-methods or alter the distribution of sub-methods that are included in a method for detecting a seizure. A sub-method may, for example, be a set of instructions which may be used to increment a counter. Sub-method, including for example, threshold values, weighting coefficients and other data, may be provided in a template file, may have a "factory default" setting, and may change as the method

adapts to a particular patient.

[0017] In some examples, the value of a plurality of seizure variables may be determined for a patient. Individual seizure variables may be selected and analyzed using algorithms such that events logged for an individual seizure variable is unlikely to trigger an alarm; however, the convolution of events logged for the plurality of seizure variables may raise the confidence with which a seizure may be detected.

[0018] In some examples, a method and apparatus may be used, for example, to initiate an alarm protocol, create a log of seizure incidents to help medically or surgically manage the patient, activate a Vagal Nerve Stimulator, or activate other stimulating devices that may be used to abort or attenuate a seizure. In some embodiments, a log of seizure related incidents may prompt a physician to understand more quickly the failure of a treatment regimen.

BRIEF DESCRIPTION OF THE DRAWINGS

[0019]

Fig. 1 illustrates one embodiment of a seizure detection system.

Fig. 2 illustrates one embodiment of a detection unit and base station for a seizure detection system.

Fig. 3 illustrates one embodiment of a base station.

Fig. 4 illustrates one embodiment of a method for detecting seizure related incidents.

Fig. 5 illustrates exemplary EMG time domain data for a patient.

Fig. 6 illustrates exemplary EMG frequency domain data for a patient.

Fig. 7 illustrates one embodiment of a burst detection algorithm.

Fig. 8A and Fig. 8B illustrate exemplary model forms or envelopes of signal bursts after filtering, rectification and peak detection.

Figs. 9A, 9B and 9C illustrate another embodiment of a burst and burst train detection algorithm

Fig. 10 illustrates one embodiment of a periodicity algorithm.

Fig. 11 illustrates one embodiment of a GTC waveform detection algorithm.

Fig. 12 illustrates a second embodiment of a GTC waveform detection algorithm.

Fig. 13 illustrates one embodiment of a waveform regularity detection algorithm.

Fig. 14 illustrates one embodiment of a supervisory algorithm.

Figs. 14A, 14B and 14C illustrate another embodiment of a supervisory algorithm.

Fig. 15 illustrates one embodiment of a method of data collection.

Fig. 16 illustrates one embodiment of a method of updating a template file.

Fig. 17 illustrates one embodiment of a method of adjusting the state of a detection unit in a method of seizure monitoring.

Fig. 18 illustrates one embodiment of an amplitude detection algorithm.

Fig. 19 illustrates a further embodiment of a method for detecting seizure related incidents.

Fig. 20 illustrates a still further embodiment of a method for detecting seizure related incidents.

Fig. 21 illustrates how model data in a procedure for analysis of data bursts may be organized.

Fig. 22 illustrates how model data for analysis of data bursts is combined with data from a GTC accumulation register and how data in those registers may be analyzed in a supervisory algorithm.

Fig. 23 illustrates exemplary EMG electrical data for a patient.

Fig. 24 illustrates exemplary EMG electrical data for a patient while non-seizure moving.

Fig. 25 illustrates exemplary EMG electrical data for a patient who is sleeping.

Fig. 26 illustrates exemplary EMG electrical data for a patient at the onset of a seizure.

Fig. 27 illustrates exemplary EMG electrical data for a patient as the seizure progresses.

Fig. 28 illustrates exemplary EMG electrical data for a patient that has been filtered.

Fig. 29 illustrates further exemplary EMG electrical data for a patient that has also been filtered.

Fig. 30 illustrates the same exemplary EMG electrical data as shown in Fig. 29 and filtered using a different filter protocol.

Fig. 31 illustrates exemplary EMG electrical data for a patient showing short-lived data events.

Fig. 32 illustrates still further exemplary EMG electrical data for a patient that has been filtered.

Fig. 33 illustrates exemplary EMG electrical data for a patient showing sustained signals.

Fig. 34 illustrates another exemplary EMG electrical data for a patient that has been filtered.

Fig. 35 illustrates another exemplary EMG electrical data for a patient.

Fig. 36 illustrates yet another exemplary EMG electrical data.

DETAILED DESCRIPTION

5 [0020] The apparatuses and methods described herein may be used to detect seizures and timely alert caregivers of a seizure using EMG, among other things. The apparatuses and method may be used, for example, to initiate an alarm protocol, create a log of seizure incidents to help medically or surgically manage the patient, activate a Vagal Nerve Stimulator, or activate other stimulating devices that may be used to abort or attenuate a seizure. In some examples, a log of seizure related incidents may prompt a physician to understand more quickly the failure of a treatment regimen. The apparatuses and methods may comprise a process and device and/or system of devices for detecting seizures with motor manifestations including, but not limited to Tonic-Clonic, Tonic-only, or Clonic-only seizures. A "motor manifestation" may in some embodiments generally refer to muscle activity, whether sustained or otherwise.

10 [0021] Apparatuses as described herein may be useful for monitoring a person to determine whether the person may be having a seizure, and for initiating an alarm. The methods described herein may be flexible, e.g., such methods may be customized for an individual. Moreover, such methods may be adaptive, and may improve as data is collected, e.g., for a given patient or for a certain patient demographic. Furthermore, apparatuses described herein may be suited for organizing and/or prioritizing the collection of large amounts of data, e.g., data that may be collected in a substantially continuous manner, such as while a seizure-prone individual is in a home setting.

15 [0022] In general terms, EMG electrode signals may be collected and processed to determine seizure variables. A "seizure variable" may in some embodiments refer to a criterion or criteria of one or more portions of data collected from the output signal of a detector. For a given set of data, a seizure variable may have one or more numerical values associated with it. For example, the amplitude of a signal may be a seizure variable that may have one or more numerical values associated with it for a given set of data. A value of a seizure variable may be compared to a threshold level and may be used as an input in an algorithm for determining whether a seizure may have occurred.

20 [0023] A processing method may include calculating one or more seizure variable values and may further include comparing such values to one or more thresholds that may characterize a seizure. Data registers may be populated based upon such a comparison, and used to evaluate whether to initiate an alarm protocol. The weighting of data in different registers, and thus the importance of different characteristics of EMG data, may be customized for an individual patient or patient demographic, and may adapt as the system obtains more information for a patient or patient demographic.

25 [0024] A variety of suitable systems may be suitable for collecting large amounts of EMG and other patient-related data, organizing such data for system optimization, and for initiating an alarm in response to a suspected seizure. Fig. 1 illustrates an example of such a system. In the embodiment of Fig. 1, a seizure detection system 10 may include a detection unit 12, an optional base station 14, an optional video monitor 9 and an optional alert transceiver 16. The detection unit may comprise one or more EMG electrodes capable of detecting electrical signals from muscles at or near the skin surface of a patient, and delivering those electrical EMG signals to a processor for processing. The base station may comprise a computer capable of receiving and processing EMG signals from the detection unit, determining from the processed EMG signals whether a seizure may have occurred, and sending an alert to a caregiver. An alert transceiver may be carried by, or placed near, a caregiver to receive and relay alerts transmitted by the base station.

30 [0025] In using the apparatus of Fig. 1, for example, a person 11 susceptible to epileptic seizures may be resting in bed, or may be at some other location as daily living may include, and may have a detection unit 12 in physical contact with or in proximity to his or her body. The detection unit 12 may be a wireless device so that a person may be able to get up and walk around without having to be tethered to an immobile power source or to a bulkier base station 14. For example, the detection unit 12 may be woven into a shirt sleeve, or may be mounted to an armband or bracelet. In other embodiments, one or more detection units 12 may be placed or built into a bed, a chair, an infant car seat, or other suitable clothing, furniture, equipment and accessories used by those susceptible to seizures. The detection unit 12 may comprise a simple sensor, such as an electrode, that may send signals to the base station for processing and analysis, or may comprise a "smart" sensor having some data processing and storage capability. In some embodiments, a simple sensor may be connected via wire or wirelessly to a battery-operated transceiver mounted on a belt worn by the person.

35 [0026] The system may monitor the patient, for example, while resting, such as during the evening and nighttime hours. If the detection unit 12 on the patient detects a seizure, the detection unit 12 may communicate via wire or wirelessly, e.g., via a communications network or wireless link, with the base station 14 and may send some signals to the base station device for more thorough analysis. For example, the detection unit 12 may process and use EMG signals (and optionally ECG and temperature sensor signals) to make an initial assessment regarding the likelihood of occurrence of a seizure, and may send those signals and its assessment to the base station 14 for separate processing and confirmation. If the base station 14 confirms that a seizure is likely occurring, then the base station 14 may initiate an alarm for transmission over the network 15 to alert a caregiver by way of email, text, or any suitable wired or wireless messaging indicator. In some embodiments, if one or more of the detection unit 12, the base station 14, or a caregiver, e.g., a remotely located caregiver monitoring signals provided from the base station, determines that a seizure may be occurring a video monitor 9 may be triggered to collect information.

5 [0027] The base station 14, which may be powered by a typical household power supply and contain a battery for backup, may have more processing, transmission and analysis power available for its operation than the detection unit 12, may be able to store a greater quantity of signal history, and evaluate a received signal against that greater amount of data. The base station 14 may communicate with an alert transceiver 16 located remotely from the base station 14, such as in the bedroom of a family member, or to a wireless device 17, 18 carried by a caregiver or located at a work office or clinic. The base station 14 and/or transceiver 16 may send alerts or messages to caregivers, or medical personnel via any suitable means, such as through a network 15 to a cell phone 17, PDA 18 or other client device. The system 10 may thus provide an accurate log of seizures, which may allow a patient's physician to understand more quickly the success or failure of a treatment regimen. Of course, the base station 14 may simply comprise a computer having installed a program capable of receiving, processing and analyzing signals as described herein, and capable of transmitting an alert. In other examples, the system 10 may simply comprise, for example, EMG electrodes and a smartphone, such as an iPhone, configured to receive EMG signals from the electrodes for processing the EMG signals as described herein using an installed program application. In further examples, so-called "cloud" computing and storage may be used via network 15 for storing and processing the EMG signals and related data. In yet other examples, one or more EMG electrodes could be packaged together as a single unit with a processor capable of processing EMG signals as disclosed herein and sending an alert over a network. In other words, the apparatus may comprise a single item of manufacture that may be placed on a patient and that does not require a base station separate transceiver.

10 [0028] In the embodiment of Fig. 1, the signal data may be sent to a remote database 19 for storage. In some embodiments, signal data may be sent from a plurality of epileptic patients to a central database 19 and "anonymized" to provide a basis for establishing and refining generalized "baseline" sensitivity levels and signal characteristics of an epileptic seizure. The database 19 and base station 14 may be remotely accessed via network 15 by a remote computer 13 to allow updating of detector unit and/or base station software, and data transmission. The base station 14 may generate an audible alarm, as may a remote transceiver 16. All wireless links may be two-way for software and data transmission and message delivery confirmation. The base station 14 may also employ one or all of the messaging methods listed above for seizure notification. The base station 14 may provide an "alert cancel" button to terminate the incident warning.

15 [0029] In some examples, a transceiver may additionally be mounted within a unit of furniture or some other structure, e.g., an environmental unit or object. If a detection unit is sufficiently close to that transceiver, such a transceiver may be capable of sending data to a base station. Thus, the base station may be aware that information is being received from that transducer, and therefore the associated environmental unit. In some examples, a base station may select a specific template file, e.g., such as including threshold values and other data as described further herein, that is dependent upon whether or not it is receiving a signal from a certain transceiver. Thus, for example, if the base station receives information from a detector and from a transducer that is associated with a bed or crib it may treat the data differently than if the data is received from a transducer associated with another environmental unit, such as, for example, clothing typically worn while an individual may be exercising.

20 [0030] The embodiment of Fig. 1 may be configured to be minimally intrusive to use while sleeping or minimally interfere in daily activities, may require a minimum of electrodes such as one or two, may require no electrodes to the head, may detect a seizure with motor manifestations, may alert one or more local and/or remote sites of the presence of a seizure, and may be inexpensive enough for home use.

25 [0031] Fig. 2 illustrates an embodiment of a detection unit 12 or detector. The detection unit 12 may include EMG electrodes 20, and may also include ECG electrodes 21. The detection unit 12 may further include amplifiers with leads-off detectors 22. In some embodiments, one or more leads-off detectors may provide signals that indicate whether the electrodes are in physical contact with the person's body, or otherwise too far from the person's body to detect muscle activity, temperature, brain activity or other patient phenomena.

30 [0032] The detection unit 12 may further include a temperature sensor 23 to sense the person's temperature. Other sensors (not shown) may be included in the detection unit, as well, such as accelerometers. Signals from electrodes 20 and 21, temperature sensor 23 and other sensors may be provided to a multiplexor 24. The multiplexor 24 may be part of the detection unit 12 or may be part of the base station 14 if the detection unit 12 is not a smart sensor. The signals may then be communicated from the multiplexor 24 to one or more analog-to-digital converters 25. The analog-to-digital converters may be part of the detection unit 12 or may be part of the base station 14. The signals may then be communicated to one or more microprocessors 26 for processing and analysis as disclosed herein. The microprocessors 26 may be part of the detection unit 12 or may be part of the base station 14. The detection unit 12 and/or base station 14 may further include memory of suitable capacity. The microprocessor 26 may communicate signal data and other information using a transceiver 27. Communication by and among the components of the detection unit 12 and/or base station 14 may be via wired or wireless communication.

35 [0033] Of course, the exemplary detection unit of Fig. 2 may be differently configured. Many of the components of the detector of Fig. 2 may be base station 14 rather than in the detection unit 12. For example, the detection unit may simply comprise an EMG electrode 20 in wireless communication with a base station 14. In such an embodiment, A-D conversion

and signal processing may occur at the base station 14. If an ECG electrode 21 is included, then multiplexing may also occur at the base station 14.

[0034] In another example, the detection unit 12 of Fig. 2 may comprise a electrode portion having one or more of the EMG electrode 20, ECG electrode 21 and temperature sensor 23, in wired or wireless communication with a small belt-worn transceiver portion. The transceiver portion may include a multiplexor 24, an A-D converter 25, microprocessor 26, transceiver 27 and other components, such as memory and I/O devices (e.g., alarm cancel buttons and visual display).

[0035] Fig. 3 illustrates an embodiment of a base station 14 that may include one or more microprocessors 30, a power source 31, a backup power source 32, one or more I/O devices 33, and various communications means, such as an Ethernet connection 34 and transceiver 35. The base station 14 may have more processing and storage capability than the detection unit 12, and may include a larger electronic display for displaying EMG signal graphs for a caregiver to review EMG signals in real-time as they are received from the detection unit 12 or historical EMG signals from memory. The base station 14 may process EMG signals and other data received from the detection unit 12. If the base station 14 determines that a seizure is likely occurring, it may send an alert to a caregiver via transceiver 35.

[0036] Various devices in the apparatus of Figs. 1-3 may communicate with each other via wired or wireless communication. The system 10 may comprise a client-server or other architecture, and may allow communication via network 15. Of course, the system 10 may comprise more than one server and/or client. In other embodiments, the system 10 may comprise other types of network architecture, such as a peer-to-peer architecture, or any combination or hybrid thereof.

[0037] Fig. 4 illustrates an exemplary a method 36 of monitoring EMG and other signals for seizure characteristics, and initiating an alarm response if a seizure is detected. Such a method may involve collecting of EMG signals, calculating one or more values of a seizure variable, and using such seizure variable data to populate processor or memory registers. In general, one or more seizure variables and one or more registers may be included in data analysis. In a step 38, EMG signals and other detector output signals may be collected. Output signals may be collected in a substantially continuous manner or periodically. Output signals may be processed in a step 40 to obtain seizure variable data. The data values may be used to populate one or more detection registers, as shown in step 42. Processing of output signals and population of detection registers may be executed during a defined period of time, i.e., collection time window. At the expiration of such a collection time window, each detection register may transfer its contents, if any, to one or more accumulation registers (as shown in step 44), and the contents of one or more detection registers, if any, may be cleared. After expiration of the collection time window, and after adjustment (increase or leakage) of accumulation registers, the cycle may repeat itself (as shown by line 46), i.e., detector output may be collected during a subsequent collection window. Periodically, a supervisory algorithm may analyze the contents of one or more accumulation registers to determine whether a seizure is likely occurring (step 48). If the supervisory algorithm determines that the sum of values or a weighted sum of values in the accumulation registers exceeds a threshold then an alarm protocol may be initiated (step 50). Alternatively, the supervisory register may determine that the contents of accumulation registers do not indicate that a seizure is likely and the system may wait for a next analysis period (step 52).

[0038] As discussed below, a supervisory algorithm may comprise a number of sub-routines that use various seizure variable values in the accumulation and/or detection registers. As shown by way of example in Fig. 4, methods may involve the population of individual detection registers with a data value and addition of such a data value to accumulation registers (steps 38, 40, 42, and 44). A sub-method may include steps involved in the population of individual detection registers and accumulation registers. Each sub-method may consider one or more characteristics of the collected data and perform process analysis on such characteristics. Individual sub-methods may include, by way of nonlimiting example, detection of signal bursts and detection of GTC waveforms. Sub-methods may process data in the time domain, the frequency domain, or, in some embodiments, process portions of data in both the time domain and frequency domain. Before discussion of those individual sub-methods in greater detail, it is helpful to consider some general aspects of data collection, the detectors used, as well as processing steps, such as data filtration that may be involved in various sub-methods. In addition, it is instructive to discuss exemplary EMG signal data, as shown in Figs. 5 and 6 discussed in more detail further herein.

[0039] As indicated in step 38 of Fig. 4, in the invention, detection of seizures is be accomplished exclusively by analysis of EMG electrode data. In other embodiments, a combination of EMG and other detectors may be used. For example, temperature sensors, accelerometers, ECG detectors, other detectors, or any combinations thereof, may be used. Accelerometers may, for example, be placed on a patient's extremities to detect the type of violent movement that may characterize a seizure. Similarly, ECG sensors may be used to detect raised or abnormal heart rates that may characterize a seizure. Thus, a monitoring device may detect an epileptic seizure without the customary multitude of wired electrodes attached to the head, as typical with EEG. Combination of EMG electrodes with other detectors may, for example, be used with particularly difficult patients. Patients with an excessive amount of loose skin or high concentrations of adipose tissue, which may affect the stability of contact between an electrode and the skin, may be particularly difficult to monitor. In some embodiments, an electrode may be attached to a single muscle, and in other embodiments a combination of two or more electrodes may be used. Electrodes may, for example, be attached to an agonist and

antagonist muscle group or signals from other combinations of different muscles may be collected.

[0040] In general, the system described herein is compatible with any type of EMG electrode, such as, for example, surface monopolar electrodes or bipolar differential electrodes or electrodes of any suitable geometry. Such electrodes may, for example, be positioned on the surface of the skin, may or may not include application of a gel, and may, in some embodiments, be Ag/AgCl electrodes. The use of a bipolar EMG electrode arrangement, e.g., with a reference lead and two surface inputs, allows for the suppression of noise that is common to those inputs. That is, a differential amplifier may be used, and a subtraction of the signals from one input with respect to the other may be accomplished, and any differences in signal between the inputs amplified. In such an approach, signals that are common to both inputs (such as external noise) may be substantially nullified and preferential amplification of signals originating from muscle depolarization may be achieved.

[0041] An EMG signal may be collected for a given time period, e.g., a time domain electrode signal may be collected. Time domain electrode data, may be converted to frequency data, i.e., spectral content, using techniques such as Fast-Fourier Transform (FFT). In reference to Fig. 4, the conversion of data between the time and frequency domain may be included in a processing step 40. Other aspects of data processing may include smoothing data, application of one or more frequency filters, fitting data in a given region to a particular function, and other processing operations

[0042] Fig. 5 (which comprises Figs. 5a and 5b) provides an example of EMG data 54 collected over a time period of about 2 seconds. The data in Fig. 5 may exemplify data collected by placing a bipolar differential electrode over the biceps or triceps of a patient. Fig. 6 illustrates some of the EMG data 54 of Fig. 5 converted to the frequency domain. The EMG data 74 in Fig. 6 may represent, for example, a one-second epoch of the EMG data 54 converted to the frequency domain. For an EMG electrode, visual representation of frequency domain data may also be referred to as a spectral graph.

[0043] Referring now to the time domain data for the graph of Fig. 5, the vertical axis or scale in Fig. 5a is signal amplitude, e.g., the differential signal between the pair of EMG electrode inputs, and the horizontal axis or scale shows time (in Fig. 5, the time window is approximately two seconds). In reference to any of the graphs described herein the term amplitude may be used, and such may refer to either the magnitude of signal, or absolute value of magnitude, as may be appropriate for a given calculation. Signals collected may, for example, be rectified, and unless otherwise noted, detection of bursts as described herein involves rectified signal data. As shown in Fig. 5, the amplitude (or absolute value of the amplitude) appears to experience a sustained increase at least three times (56, 58, and 60) during the 2-second period. Such sustained increase may be indicative of what is referred to as a burst, or signal or data burst. As discussed in more detail below, fluctuations in time periods between suspected bursts, such as 66 or 68, may be used to calculate a baseline. Fluctuations in a baseline region, i.e., noise, may be related to a peak to peak value, a root mean square (RMS) value or other metric. Fig. 5b illustrates a portion of the EMG data 54, namely, the region of data including burst 60 and adjacent period. In Fig. 5b, a RMS noise value 72 and amplitude 70 are indicated. The signal-to-noise ratio (SNR or S/N) of burst 60 is, in this example, about 4:1, i.e., amplitude 70 is about four times larger than the noise value 72. The EMG data of Fig. 5 is discussed in further detail with regards to a burst detection sub-method in Fig. 7.

[0044] Referring now to the exemplary data of Fig. 6, the vertical scale represents the magnitude of a given frequency (which may be referred to as spectral density) and the horizontal scale is signal frequency. Note that the spectral data in Fig. 6 indicates a curving slope with decreasing magnitude as the frequency increases, i.e., the spectral density generally decreases as the frequency increases. The ratio of spectral density at a lower frequency to the spectral density at a higher frequency may be a seizure variable that, for any given portion of electrode data, may have an associated value. For example, for the data shown in Fig. 6 the ratio of spectral density at a frequency of about 200 Hz (76) to the spectral density at about 400 Hz (78) may have a value of about 1.1.

[0045] Also, as illustrated in the expanded portion of the same data in Fig. 6b, which shows at least a portion of the characteristic GTC waveform, a region of elevated spectral density 80, i.e., a relatively high-frequency "bump" between approximately 300-500 Hz, and particularly around 400 Hz 82 is shown. That is, the spectral density 80 at frequency 82 in that region is elevated above the spectral density 84, e.g., within a "slumped" region, approximately located at a frequency 86 of about 300 Hz. The term "slump region" or "slump" may in some embodiments refer to a portion of spectral data generally possessing the property of having positive curvature, i.e., a slump region refers to a local minimum in a set of data. The term "bump region" or "bump" may in some embodiments refer to a portion of spectral data where the data generally possesses the property of having negative curvature, i.e., a bump region refers to a local maximum in a set of data. To generally possess a positive or negative curvature means that local fluctuations in individual data points may be averaged or smoothed out of the data. That is, neglecting local fluctuations, e.g., due to noise, a data set may possess a property of curvature.

[0046] The ratio of spectral density at a frequency 86 to the spectral density at a frequency 82, or slump to bump ratio, may be used as a seizure variable. In some examples, the slump to bump ratio may be used as a metric for detection of a GTC waveform. However, more advanced data analysis techniques, e.g., looking at a greater number of data points and/or advanced pattern recognition algorithms, may also be used to identify a GTC waveform. In some examples, a detection unit may include instructions for calculation of a slump to bump ratio and a base unit may calculate a slump

to ratio and also corroborate the slump to bump calculation with more advanced pattern recognition analyses. The EMG data of Fig. 6 and the above data features are discussed in further detail with regards to a GTC waveform detection sub-method as described, for example, in Figs. 11 and 12.

5 [0047] Referring back to Fig. 4, the collection of EMG data may be accomplished with a detection unit and that detection unit may execute an initial analysis and processing of data. In some embodiments, if the detection unit determines that a seizure is likely occurring, it may send data to a base station, where further processing may occur. Thus, a detection unit, a base station or both may process EMG signals, and either or both devices may execute a seizure detection sub-method. Such a sub-method may characterize particular features of EMG data, and may, based upon such a characterization, direct the transfer of data between data registers and accumulation registers. Those aspects of sub-methods, 10 such as described herein in reference to Figs. 7 and 10-13, may involve aspects of steps 38, 40, 42, 44, and 46 of method 36. A sub-method may feed data into a supervisory algorithm.

15 [0048] Fig. 7 illustrates one example of a sub-method 88 which may be used for analysis of data bursts. In a step 90 of Fig. 7, a detection unit and/or base station may select a protocol for analysis of data bursts. The selection of an analysis protocol may, for example, be indicated in a template file. Such a template file may include instructions to choose a routine to smooth data, a routine to filter data, a routine to treat the data in some other manner or combinations of routines thereof. Such routines may be executed by either the detection unit, base station or both. The analysis protocol may include a peak detection program, which, for example, after band-pass filtering and rectification may identify and shape a data burst, as shown in the examples of Fig. 9 and Fig. 10. Any suitable peak detection technique may be used (e.g., continuous wavelet transform), and may in some embodiments include, for example, data smoothing techniques (e.g., moving average filter, Savitzky-Golay filter, Gaussian filter, Kaiser Window, various wavelet transforms, 20 and the like), baseline correction processes (e.g., monotone minimum, linear interpolation, Loess normalization, moving average of minima, and the like) and peak-finding criteria (SNR, detection/intensity threshold, slopes of peaks, local maximum, shape ratio, ridge lines, model-based criterion, peak width, and the like).

25 [0049] A peak detector may have separate attack and decay rates. These rates may be individually adjusted. Since there frequently may be plenty of sustained amplitude during a real burst, fear of the peak detected signal decaying too quickly during bursts is generally not a problem. Therefore, the decay rate may be set to decay rather quickly following a burst. Usually the time between bursts is longer than the burst itself, and so there may be no reason to speed up the decay. However, a noise spike between bursts could artificially cause the peak detector output to jump up to a level that would make distinguishing real seizure bursts a problem. Therefore, the attack rate may be carefully controlled to prevent 30 this from occurring.

[0050] In step 91 of the method of Fig. 7, a burst detection algorithm may be initiated. Burst analysis may be triggered, for example, by detection of an EMG signal having an amplitude value that meets or exceeds a burst analysis amplitude threshold. Within the burst detection window, the EMG data may be analyzed for elevated amplitude using, e.g., a peak detection program. Regions of elevated amplitude may be classified as potential bursts. For example, referring back to 35 Fig. 5, at least three periods of sustained elevation of amplitude (56, 58, and 60) may be identified in the approximately 2-second epoch. Regions of elevated amplitude within the burst detection window may be measured for amplitude, width, and a SNR may also be determined. A portion of data, e.g., identified as a possible peak, may have amplitude associated with it, e.g., peak amplitude, median, mean or other metric may be calculated.

40 [0051] In step 92 of Fig. 7, EMG signal data, such as within a certain time period (burst detection window), may be analyzed for bursts. For example, for suspected data burst 56, amplitude 62 may be measured. A burst may have an amplitude that is elevated over surrounding portions of data, and that elevated amplitude may extend for a period of time. That is, a burst may have a burst width, such as burst width 64. To determine a burst width, a leading edge of a burst and a trailing edge of a burst may be determined. To detect the leading edge and trailing edge of a burst, changes in amplitude for successive data points may be measured, e.g., the rate of change of amplitude with time may be 45 calculated. Any other suitable technique, such as those described above, may be used, as well. In some embodiments, burst width may be categorized by calculating, for a region of time, whether a threshold minimum amplitude is met at a given probability, e.g., where a majority of points show elevated amplitude above some threshold.

[0052] Signal to noise calculations may involve, for example, establishing a baseline by determining fluctuations in detector signal, i.e., baseline noise, in a time period immediately prior to data in a time suspected of containing bursts. 50 For example, an EMG signal may be relatively quiet in the time leading up to a seizure, as discussed in more detail in connection with Fig. 25, below. That quiet period may be used to establish a baseline.

55 [0053] A baseline may also be established by looking at fluctuations between burst periods within the same time window suspected of having bursts. For example, referring back to the EMG data of Fig. 5, data fluctuations in time periods between suspected bursts, such as the data in the time periods 66 or 68, may be used to calculate a baseline. Fluctuations in a baseline region, i.e., noise, may be related to a peak to peak value, a RMS value or other suitable baseline detection metric. In Fig. 5 an expanded region of data, i.e., the region of data including burst 60 and adjacent period, is shown in Fig. 5b, and a root mean square noise value 72 and amplitude 70 are approximately indicated. The S/N of burst 60 may, for example, be about four, i.e., amplitude 70 is about four fold larger than the noise value 72.

[0054] It should be noted that the baseline established by looking at fluctuations between burst periods may be different than the baseline established by looking at a pre-seizure quiet time. Thus, different peak detection algorithms may be run for each, or the same algorithm may be ramped up or down with respect to baseline detection depending on whether detecting quiet time or seizure activity. For example, a baseline detector may be a peak detector having a much longer time constant than a peak detector used for signal envelope generation. This baseline detector may rise up to a higher level during a tonic phase but may ramp down during a clonic phase of activity. A negative peak detector may also be employed to ramp a baseline detector down more quickly during relatively quiet times so as to distinguish the bursts more readily.

[0055] In step 94, the burst detection algorithm may determine if the EMG signal data within a burst detection window meet various requirements or thresholds or other criteria to qualify regions of elevated amplitude as bursts. For example, the algorithm may determine whether one or more regions of elevated amplitude meet requirements for amplitude, width, and time between regions of elevated amplitude to qualify as seizure bursts. For example, a sub-method for detecting bursts may detect amplitudes above a certain threshold that are closer than Y seconds apart and farther than Z seconds apart. Such requirements (or burst criteria) may be provided in a template file. For example, referring to Table 1, the minimum S/N criteria may be pulled from the template file and compared to the calculated value of S/N for each suspected burst.

[0056] Generally, a burst may be characterized by a sudden increase in the amplitude of the EMG electrode signal from a lower amplitude level, maintenance of that increased amplitude level for a specified minimum amount of time, return of the amplitude level to a lower level of electrode signal after no more than a specified maximum time, and maintenance of the lowered amplitude level for a specified minimum time. Fig. 8A and Fig. 8B illustrate exemplary model forms or envelopes of signal bursts after filtering, rectification and peak detection. Generally, the lower amplitude signal level may not go to zero. The lower amplitude above zero is signal noise. The ratio of the burst amplitude level to the noise level is the SNR. For example, if the signal level of the burst is 1 volt, and the noise is 0.35 volts, then the SNR would be $1/0.35$, or 2.86. In the example of Fig. 8, the peak amplitude 120 of EMG signal data may be compared to criterion associated with peak amplitude. If the amplitude 120 is greater than a minimum amplitude criterion 120a, and less than a maximum amplitude criterion 120b, then the ratio of peak amplitude to the level of noise 102 may be determined and compared to a burst amplitude criterion, e.g., a SNR threshold. If the peak amplitude meets the SNR threshold, then the EMG signal data may qualify as a burst (or the start of a burst) with respect to amplitude. A maximum burst amplitude requirement may be helpful in eliminating from consideration elevated amplitude EMG data caused from external noise sources that may introduce amplitude well above the amplitudes capable of being produced by the human body.

[0057] Fig. 8A also shows the region of elevated amplitude as having a width 114 is shown. The width 114 may be compared to a minimum burst width (dashed line 116) and a maximum burst width (dashed line 118). As may be seen in Fig. 8B, the width 114 falls between the minimum and maximum burst width thresholds, and thus qualifies the region of elevated amplitude as a burst with respect to width. A maximum burst width requirement may be helpful in eliminating from consideration elevated amplitude EMG data that is from voluntary muscle activity, a noise source or is caused by electrode connectivity problems. That could help eliminate falsely identifying real or apparent high-amplitude muscle activity as a seizure.

[0058] Fig. 8B shows examples of two successive bursts (104 and 106) separated by a time period 108. In Fig. 8B the time between bursts 108 may, for example be compared to criterion values associated with a minimum period between successive bursts (dashed line 110) and a maximum period between successive bursts (dashed line 112). If a sufficient quantity of bursts succeed each other within the minimum and maximum time periods, then successive bursts may qualify as a burst train indicative of a seizure. However, not all burst trains indicate a seizure, and a periodicity algorithm (discussed in more detail below) may be used to further evaluate the likelihood that a seizure is occurring. For example, extremely regular bursts may not indicate a seizure. Sporadic bursts may not indicate a seizure, either, or if spaced sufficiently far apart, represent minimal threat of imminent harm from seizure.

[0059] After reaching the end of the burst detection window, the burst detection algorithm may wait for a delay period before analyzing data in a subsequent burst detection window. By adding a delay, the burst detection algorithm may ensure that new data is analyzed. If analysis of a burst window, or analysis of one or more successive burst detection windows reveals no bursts or near-bursts, then the burst detection sub-method may pause, as seen at step 95, until the burst analysis amplitude threshold triggers activation of the sub-method.

[0060] The burst amplitude, width and periodicity values may be stored in registers for use by a supervisory algorithm to determine the likelihood of a seizure occurring. If the supervisory algorithm determines that a seizure is occurring, then it may declare an alarm, and cause the base station 14 to send an alert to a caregiver.

[0061] Criterion values may, for example, be included in a template file. More specifically, Table 1 lists exemplary criteria that that may be included in a template file which may be used in a sub-method for evaluation of data bursts. Each criterion may be a variable that may be changed to adjust the sensitivity of the seizure detection method. Of course, not all of the criteria need be used. For example, maximum burst amplitude may be considered optional if unduly limiting

for a particular patient. Likewise, additional criteria may be used. For example, if signal amplitude is sufficiently high to trigger the burst detection sub-method, but does not quite meet the minimum burst amplitude even though it meets burst width criteria, then its variance from the minimum burst amplitude may be negatively weighted by a certainty value criterion. A certainty value criterion may be, for example, a percentage value. If the measured amplitude is 95% of the minimum burst amplitude, then the certainty value may be set accordingly. If successive bursts have sufficient periodicity to qualify as a burst train, the negatively-weighted burst may be included in the train to further test periodicity. If a certain number of negatively-weighted bursts appear in the data, then a supervisory algorithm may lower the minimum burst amplitude thresholds to increase the sensitivity of the burst detection method for the particular patient being monitored. Similar weighting may be done with respect to signal values that do not quite meet the other burst criteria. Certainty values may be used by the burst detection method, other sub-methods described herein, and the supervisory algorithm.

TABLE 1: Template data for a burst detection sub-method

Variable	Value / unit	Type
Burst analysis minimum amplitude threshold	XX amplitude	Criterion for initiation of burst detection algorithm
Burst detection window	XX seconds	Routine selection
Delay between adjacent burst detection windows	XX seconds	Routine selection
Minimum burst width	XX seconds	Criterion for burst count
Maximum burst width	XX seconds	Criterion for burst count
Burst envelope peak detector attack rate	XX	Routine selection
Burst envelope peak detector decay rate	XX	Routine selection
Minimum burst amplitude	XX amplitude	Criterion for burst count
Maximum burst amplitude	XX amplitude	Criterion for burst count
Minimum S/N	XX	Criterion for burst count
Minimum period between successive bursts	XX seconds	Criterion for burst count
Maximum period between successive bursts	XX seconds	Criterion for burst count
Decay rate	XX	Data feature / weighting coefficient
Decay rate (S/N) modifier	XX	Data feature / weighting coefficient
Selection of filter protocol (if applied)	XX	Routine selection
Selection of smoothing protocol (if applied)	XX	Routine selection
Calculation method	XX	Routine selection
Baseline calculation method	XX	Routine selection
Coefficient (combination with supervisory algorithm)	XX	Weighting coefficient

For clarity, the "XX" is simply a value placeholder, and should not be construed to connote magnitude or precision in any way.

[0062] Referring back to Fig. 7, in a step 96, one or more detection registers may be loaded with burst values for a detection window. For example, a burst count register may be used to contain a value corresponding to the number of detected bursts within the burst detection window. For example, if the two-second time period of Fig. 5 was a burst detection window, then the EMG data within that window may be analyzed for bursts. In Fig. 5, for example, the EMG signal data shows three bursts. Thus, a value of 3 may be stored in the burst count register. Other registers may be used to store other burst values, such as amplitude, periodicity, width, certainty values, and so forth.

[0063] Following each burst detection cycle, e.g., analysis of a burst detection window, the detection register may, in some embodiments, add its contents to one or more burst accumulation registers (step 98). Before analyzing the data in subsequent burst detection windows, the detection registers may be cleared to allow storage of burst data for the subsequent burst detection windows. The detection registers may then begin storing burst values during another cycle, or, in some embodiments, begin counting bursts after a certain delay period.

[0064] In some examples, the EMG signal data may be written to a circular buffer in RAM in the device hardware. One advantage of such a strategy may be that less RAM is used because the processed data may store only a pattern of the data, such as peak detected values, and not a point by point data file of full signal data. That is, a voltage (or other electrical parameter that reflects amplitude of the detection unit) at each corresponding point in time need not be stored. For example, in some embodiments, only the data necessary to derive a model form such as indicated in Fig. 8 and Fig. 9 may be stored. It should be appreciated in those figures that noise in regions between detected bursts is depicted to be maintained at a constant level. Thus, only a calculated value of the noise, e.g., such as RMS amplitude (102), may be stored and not all of the individual fluctuations in the baseline data. Thus, the data file in RAM may be significantly compressed. In some examples, as opposed to storing a compression of the data in a time window, all raw data from a given window may be stored in a circular buffer in RAM. It should thus be appreciated that an algorithm may look at any given preceding time window at any point in the algorithm. Such may be used, for example, to consider how any given value of EMG data has changed between one or more time windows.

[0065] In some examples, each burst may be weighted with a value that is not only related to detection of a burst but also related to the certainty of burst detection. Certainty values may, for example, be related to the normalized amplitude or the ratio of the normalized amplitude to detector noise. For example, a signal burst may be characterized by transition from approximately 100% of the normalized amplitude to approximately 35% of the normalized amplitude. The certainty value may be approximately 65, which number may be loaded into a register whose maximum value could be approximately 100.

[0066] As denoted in step 97, one or more of the detection registers may add their contents to one or more accumulation registers. For example, a burst count detection register may add its value to the a burst count accumulation register.

[0067] In step 98, the accumulation registers may, in addition to accepting a data value from the detection register, adjust the value of any previous data which may be held. For example, in some embodiments, the burst count accumulation register may hold a value that is related to the quantity of bursts collected in a preceding number of burst detection cycles. That is, each time the burst count detection register adds contents from one cycle, the burst count accumulation register may remove a data value that was added during some preceding cycle. Thus, the burst count accumulation register may, in some examples, act as a moving sum based on the sum of counts from a number of preceding burst detection windows. In such an example the computer may store in memory, e.g., in any number of additional registers, the appropriate data value to add or subtract from the burst count accumulation register. In other examples, at the completion of a cycle, the burst count detection register may add any contents, e.g., value of collected bursts, to the burst count accumulation register and then remove a certain value, i.e., it may leak at a certain rate. A leakage rate, or decay rate as shown in Table 1, may be included in a template file and may be adjusted to customize the burst detection sub-method to a particular patient or patient demographic. In some examples, the leakage rate may be a value that is modified based upon another criterion. For example, the burst count accumulation register may if one or more successive burst detection windows do not contain any bursts.

[0068] In other examples, the rate of decay of the burst count accumulation register may depend upon the S/N of bursts counted in one or more given time window. In further examples, the burst count accumulation register may be modified based on how the S/N of bursts is changing. That is, the average S/N of detected bursts may be tracked, e.g., the average S/N value of bursts in given time windows may, at least for some period of time, be stored in memory, such as in a circular RAM buffer. If the S/N of bursts changes between time windows, such a change may be analyzed, and used to modify the decay rate of the burst count accumulation register. In general, if the S/N of bursts is increasing the decay rate of the burst count accumulation register will drop by some factor and if the S/N of bursts is decreasing the decay rate of the burst count accumulation register will increase by some factor. In addition, during step 98 the contents of the burst count accumulation register, may decay in a manner that is dependent upon various negative weighting factors. For example, if no bursts are detected in a cycle, such may be an indication that a seizure is not occurring, and the rate of decay of the burst count accumulation register may be adjusted. Again, to analyze data in preceding time windows, either point by point data or a model shape may be stored in a circular buffer of RAM in the system hardware. Referring back to Fig. 4, the value stored in the burst count accumulation register is an example of one value that may be examined with a supervisory algorithm.

[0069] In step 99, the burst detection algorithm may wait for a time period equal to the burst detection window delay value before analyzing EMG signal data in subsequent burst detection windows. The burst detection registers may be cleared in step 100 before analyzing EMG data in the next burst detection window. In some embodiments, the burst detection algorithm may continue to run until it finds one or more burst detection windows that do not contain any bursts or near-bursts, or until the supervisory algorithm triggers an alarm.

[0070] In general, the presence of qualified bursts, and a large value being stored in the burst count accumulation register, may increase the probability that a seizure event is declared. It is also an aspect of methods described herein, negative weighting factors may be used, for example, with respect to signal characteristics that diminish the likelihood that a seizure is occurring. For example, as discussed above, different negative weighting factors, such as the absence of bursts in a preceding time window, or a decreasing S/N may influence the leakage rate of an accumulation register.

[0071] Figs. 9A, 9B and 9C illustrate another example of a burst and burst train detection algorithm. The flowcharts of Figs. 9A-9C show logic flow, not actual routines. In an actual routine, they would be called by the supervisory algorithm or be scheduled as one-time passes by timer interrupt, not infinite loops. There are two main routines, the burst detection algorithm (Figs. 9A and 9B), and the burst train detection algorithm (Fig. 9C). The burst detection algorithm looks for a burst that meets the requirements of amplitude (both min and max) and minimum width. If the minimum spacing between detected bursts is too small, the burst train detection algorithm will catch it. A burst train detection algorithm may rely on a periodicity algorithm, as discussed below.

[0072] In Fig. 10 an additional exemplary algorithm 113 (the periodicity algorithm) is described that according to the invention, acts to suppress the initiation of a seizure alarm. The periodicity algorithm accomplishes this task by looking at the circular buffer over a time frame and examining how regular the detected bursts were. A periodicity algorithm may scan different the data values from various time windows that the burst detection algorithm wrote into a circular buffer, and examine the periodicity of signal characteristics, including those that may not be indicative of a seizure.

[0073] In some embodiments, variables in the periodicity algorithm may be:

- Periodicity Time Window (in seconds)
- Minimum Average (or Standard) Deviation Allowed (percentage)

[0074] The periodicity time window variable is the period of time over which the periodicity algorithm scans data. For example, the periodicity time window may be sufficient to include some number of burst detection windows from the burst detection algorithm. The Deviation Allowed variable is the minimum value of how far from a single frequency the bursts may be distributed to qualify as a seizure. If the bursts huddle too closely around a specific frequency, for example 1Hz, then that burst train may not indicate a real seizure. In some embodiments, values for the periodicity algorithm may be empirically selected for default. This variable could be altered based upon patient history, experience, patient modeling and learning, and/or human feedback. In some embodiments, a patient may, for example, partake in different activities, such as, for example brushing teeth, exercising, walking or other activities to collect data that may be used to establish defaults for the periodicity algorithm.

[0075] In step 115 of the exemplary method of Fig. 10, the average duration of the period between bursts within the periodicity time window may be calculated. In step 117, each actual duration of the value of each such time period may be subtracted from the average time value, and the absolute values of the differences used to calculate, in step 119, the average deviation of the periods, and convert the average deviation to a percentage.

[0076] In step 121 the average deviation percentage may be compared to threshold values. Such threshold values may be taught to the system in operation and may be customized for the particular environment that an individual may commonly occupy.

[0077] For example, if in a periodicity time window (measuring in seconds), nine bursts were detected at the following times:

12, 13, 13.75, 14.35, 15, 15.8, 16.2, 16.5, 17.4

there would be 8 time periods between bursts. So, over a periodicity time window including the foregoing epoch of 5.4 seconds, there were nine bursts with eight periods between bursts. The average period may be calculated as $5.4/8=0.675$ seconds per burst. The time periods between bursts are as follows:

13-12=1
 13.75-13=0.75
 14.35-13.75=0.6
 15-14.35=0.65
 15.8-15=0.8
 16.2-15.8=0.4
 16.5-16.2=0.3
 17.4-16.5=0.9

In this example, a simplified method allows the time around which a burst is centered to serve as a time stamp for that burst. In other words, each time the burst algorithm qualifies a burst, a time stamp may be written into a circular buffer for use by the periodicity algorithm. In other embodiments, real burst width may be used to calculate the actual length of the time periods between bursts. For example, if the burst occurring at 12 seconds lasted for 0.02 seconds, then the time period between the burst starting at 12 and the burst starting at 13 would be 0.98 seconds. The absolute value of the deviations from the average may be calculated as follows:

EP 2 627 244 B1

1-0.675=0.325
0.75-0.675=0.075
0.675-0.6=0.075
0.675-0.65=0.025
5 0.8-0.675=0.125
0.675-0.4=0.275
0.675-0.3=0.375
0.9-0.675=0.225

10 Averaging the absolute values may be accomplished as follows:

Sum of all deviations : $0.325+0.075+0.075+0.025+0.125+0.275+0.375+0.225=1.5$

Average deviation: $1.5/8=0.1875$

15 The percentage deviation of this average is: $0.1875/0.675=27.8\%$. That is a significant deviation from the average and is unlikely to be artificial. If the Minimum Average Deviation Allowed variable is set, for example, to 15%, then the periodicity algorithm would declare that confidence is high that this is a seizure and would not vote against declaring that a seizure alarm. The result may be placed in a register for use by the supervisory algorithm.

20 **[0078]** In another simplified example, the burst train could look like this (in seconds):

17, 17.5, 18.02, 18.51, 19.04, 19.56, 20.1, 20.6, 21.13

25 So, over a periodicity time window including the foregoing epoch of 4.13 seconds, there were nine bursts with eight periods between bursts. The average period may be calculated as $4.13/8=0.51625$ seconds per burst. The individual times between bursts are as follows:

17.5-17=0.5
18.02-17.5=0.52
30 18.51-18.02=0.49
19.04-18.51=0.53
19.56-19.04=0.52
20.1-19.56=0.45
20.6-20.1=0.5
35 21.13-20.6=0.53

The absolute value of the deviations from the average are as follows:

0.51625-0.5=0.01625
40 0.52-0.51625=0.00375
0.51625-0.49=0.02625
0.53-0.51625=0.01375
0.52-0.51625=0.00375
0.51625-0.45=0.06625
45 0.51625-0.5=0.01625
0.53-0.51625=0.01375

The sum of all deviations may be calculated as follows:

50 $0.01625+0.00375+0.02625+0.01375+0.00375+0.06625+0.01625+0.01375=1.6$

The average deviation is therefore: $1.6/8=0.02$

55 The percentage deviation of this average is thus: $0.02/0.51625=3.87\%$. This example thus shows a very regular pattern. If the Minimum Average Deviation Allowed variable was set to 15%, then the algorithm would declare that confidence is very low that a true seizure is occurring and would vote against declaring a seizure alarm. The result may be placed in a register for use by the supervisory algorithm.

[0079] Of course, standard deviation calculations may be substituted for average deviation calculations for a more

statistically accurate result.

[0080] The supervisory algorithm may use the results of the values provided by the periodicity algorithm. That is, in steps 123 or 125 the algorithm may add either a positive or negative value to the supervisory algorithm. The particular value added may depend upon comparison to thresholds in step 121. The value added to the supervisory algorithm may, in some embodiments, depend not only on the particular decision, at step 121, but also on the certainty in which the decision was qualified. In addition, the value added to the supervisory algorithm may depend on other features measured. For example, characteristic patterns in an environment may not only have a certain periodicity they may also have certain amplitude. For example, an algorithm may learn that a certain period is typically identified with a certain signal amplitude and when those characteristics are viewed together, an additive or super-additive value may modulate the supervisory algorithm.

[0081] In a real seizure, the bursts can look like they are spaced evenly. However, these are generated by the body and may be only rarely evenly spaced. Real seizures are generally characterized by some variance in the spacing between bursts. Other sources of signals, that is, sources that are not derived from seizure muscle activity, may be picked up by the EMG electrodes. For example, mechanical vibration of the room or bed could result in a rhythmic vibration of the arm or other muscle to which the electrodes are attached. This could cause signals which may be picked up from the electrodes and may have an elevated amplitude. However, these signals may be very regular in frequency. Likewise, regular voluntary body movements, such as from brushing teeth, may produce bursts that look like a seizure. Whatever the source of interference at the electrodes that may look like bursts, the periodicity algorithm evaluates the periodicity of pseudo-bursts as being too regular and therefore not indicative of a seizure.

[0082] Fig. 11 illustrates one embodiment of another sub-method that may also contribute a value that may be that may be examined with a supervisory register. In Fig. 11, one embodiment of a GTC waveform detection algorithm 130 is illustrated. Fig. 12 illustrates another embodiment of a GTC waveform detection algorithm 146. As previously described, in some embodiments, the detection unit and the base station may analyze data in the same or different ways. The embodiment of Fig. 10 may, for example, be useful as an initial screen of data, i.e., it may be used to determine whether a data set is sent to a base station. The embodiment of Fig. 12 may, for example, involve the comparison of a spectral shape to a large number of files stored in memory and may be executed by a base station.

[0083] In a step 132, as shown in Fig. 11, a detection unit and/or base station may select an analysis protocol. The selection of an analysis protocol may, for example, be indicated in a template file. Such a template file may include instructions to choose a routine to smooth data, a routine for data filtration, a routine to treat the data in some other manner, or combinations of routines thereof. Such routines may be executed at various steps in sub-method 130. In a step 134, data may be collected and FFT methods may be used to convert data between the time and frequency domains. In collection of EMG data, suitable sample rates may be used as appropriate, for example, to avoid aliasing of the frequency domain data. In a step 136, the frequency value associated with a local minimum value and a local maximum value of the power density may be determined. To accomplish such, the data may typically be smoothed and a parabolic function fit to the data in a frequency region suspected of being a local maximum. In attempting to find local extreme values, the sub-method may find that the EMG data does not meet criteria to be classified as a GTC waveform. For example, the sub-method may find that in a given region expected to show a local maximum or local minimum value, the data does not exhibit such behavior.

[0084] The sub-method may, if local maximum and local minimum values are found, calculate the area under the power density/frequency curve for a region associated with the determined local extreme values (step 138). For example, the program may calculate the area under a region of 10 Hz centered on the determined local maximum and also calculate the area under a region of 10 Hz centered on the determined local minimum. The ratio of these areas may be calculated, i.e., a slump to bump ratio may be calculated, in a step 140, and compared to a threshold ratio, e.g., minimum and maximum threshold for acceptable slump to bump ratios. If the slump to bump ratio is within the threshold bounds a value may be added to a GTC detection register in a step 142. The value added to the GTC detection register, may, in some embodiments, be related to the certainty in which the slump to bump ratio was detected. In a next step 144, the value of the GTC detection register may be added to a GTC accumulation register. That is at the completion of a cycle, i.e., after each GTC collection window, the GTC detection register may add any contents, e.g., a value reflecting a detected slump to bump ratio, to the GTC accumulation register. In some embodiments, the GTC collection window may be the same as the burst detection window, i.e., the GTC waveform detection algorithm may analyze the same data that the burst detection algorithm analyzes. The GTC accumulation register may then be changed by a certain value, e.g., it may leak at a certain rate.

[0085] Referring to Fig. 12, in a step 148, another embodiment of the waveform detection algorithm may, for example, create an image in memory representing the spectral content of the EMG signal over a certain period of time. For example, one or more detectors may collect data over a certain time window and then that data may be converted to the frequency domain for spectral analysis. In a step 150, the waveform detection algorithm may evaluate the image, e.g., spectral data, and look for a characteristic GTC waveform. Any number of spectral regions, such as a high frequency region of the spectrum may be analyzed. In a step 152, a GTC accumulation register may be populated in a manner

that depends on how the spectral data compares to a stored GTC waveshape template.

[0086] Fig. 13 illustrates one embodiment of a waveform regularity detection algorithm 154. Like a periodicity algorithm, a waveform regularity detection algorithm may be used to determine if bursts are too regular in waveform to originate from seizure activity. In a step 156, the amplitude and burst width of EMG signal data during a time period may be determined. This may be accomplished in much the same way as described in for the burst detection algorithm. In a step 158 a waveform may be calculated, e.g., data from a sub-period of time around a burst may be converted to the frequency domain and a waveform calculated. The waveform may be calculated and compared to waveforms that were collected for other bursts in the time period. In some embodiments, if those waveforms are too uniform, e.g., identical or very similar in at least some characteristics, then a regularity accumulation register may be incremented. Differences between waveforms may be calculated in a manner similar to that of a periodicity algorithm, e.g., by determining an average waveform, calculating the average deviation of each waveform, and determining the percentage difference of the average deviation from the average waveform. If that percentage difference falls below a regularity threshold requirement (another variable), then a regularity detection register may be populated. In succeeding detection cycles, the regularity detection register may add its contents to a regularity accumulation register. In some embodiments, the waveform may look for uniformity within a given time period by converting data collected over that time period to the frequency domain and detecting a spike in amplitude over a very narrow frequency range. In a step 150, if the waveform regularity decreases then the regularity accumulation register may decay. As previously noted, some seizure variables may either enhance or weigh against the declaration of an alarm. In some embodiments, the value a regularity accumulation register may serve to suppress the declaration of an alarm. Referring back to Fig. 4, the values stored in either GTC accumulation register of sub-methods 130 or 146, or the value stored in the regularity accumulation register, such as described in sub-method 160, may be a value that may be used by a supervisory algorithm.

[0087] The value stored in all or some of the above referenced accumulation detection registers, e.g., such as described in relation to Figs. 7, 11-13, and 18, or input from other algorithms, e.g., as discussed in Fig. 10. According to the invention, they are periodically evaluated, such as in a step 48 of Fig. 4, which describes the use of a supervisory algorithm. The supervisory algorithm is be the overall seizure detection program running in the processor of a device in the seizure detection system 10, such as the detection unit 12 or base unit 14. Among other things, the supervisory algorithm determines whether a seizure is in process. The supervisory algorithm accomplishes this by evaluating the conclusions of the other sub-methods or algorithms that analyze EMG signal data, and perhaps other data such as temperature or heart rate, as well. A supervisory algorithm may convolute data in one or more registers that correspond to seizure variables. For example, as discussed above, a sub-method may, e.g., identify a specific characteristic of data, calculate a certainty value, and increment a register value. A supervisory algorithm then takes the register values and multiplies each value by a coefficient (e.g., from zero to one) to give more weight to certain seizure variables, and then may add all of the resultant products together. If the sum of the products exceeds a threshold value, then a seizure is declared as detected, and an alert sent accordingly. For example, an example would be $TOTAL = a(\text{register } 1) + b(\text{register } 2) + \dots + z(\text{register } 26)$. If TOTAL ever goes over the detection threshold, then a seizure detection may be declared.

[0088] Fig. 14 illustrates one embodiment of a supervisory algorithm 162. In a step 164, the supervisory algorithm periodically evaluates one or more of the detection and accumulation registers. That is, the supervisory algorithm may determine the value stored in such registers. In a step 166, the supervisory algorithm multiplies or convolutes in some other manner, the value in each register by an appropriate weighting coefficient. Such weighting coefficients may, for example, be associated with a template file. For example, table 1 indicates a coefficient that may be used to adjust the value of the burst count accumulation register. A sum of the values in accessed detection and accumulation registers may be added together in a step 168. In a step 170, the sum determined in step 168 may be compared to an overall threshold. If the sum is larger than the threshold, then a seizure alarm protocol may be initiated (step 172). In some embodiments, a supervisory algorithm may evaluate the output of a portion of the registers. For example, one or more registers may be evaluated, convoluted with coefficients, compared to a threshold, and if appropriate, an alarm protocol may be initiated. In some embodiments, the coefficient by which one seizure variable is modified may depend upon the value of another seizure variable. For example, the system may learn that when two seizure variables are simultaneously elevated, or related in some other way, that the system may detect a seizure with higher confidence.

[0089] Fig. 14A illustrates another embodiment of a supervisory algorithm. A supervisory algorithm may analyze the processed EMG data with respect to a different seizure characteristics. A supervisory algorithm may integrate or average over time its results and continually update its conclusions. This may serve to remove short glitches or spikes in the data that could lead to a false positive. In the embodiment of Fig. 14A, the supervisory algorithm uses register values from some of the foregoing sub-algorithms as follows:

- Burst Train Detect flag and Certainty value
- Periodicity good or bad and Certainty value
- GTC waveform Detect and Certainty value

In this example, each sub-algorithm could produce a flag indicating a detection. In the invention, thus in the case of the periodicity, a flag that votes against detection may be produced. Each may have a coefficient or multiplier variable (A, B, C, D) that establishes each sub-algorithm's importance or weight in the overall determination of seizure declaration. As discussed above, certainty values may range from 0 to 100%, with 100 being the highest certainty. The supervisory algorithm uses the Certainty Value to gauge confidence in the results of the Burst Detection algorithm.

[0090] Generally, a Certainty value may be used by one algorithm to transmit to another algorithm how certain the first algorithm was in its judgment. For a burst detection algorithm, for example, one metric may be the average SNR during the burst normalized to a max value of 50. Another metric may be how closely the burst looks like an ideal burst, e.g., through waveform regularity analysis. A burst that is barely greater in width than the minimum may not rate as high as one 5 times wider than the minimum. Also, a burst that is too close to the maximum may given a lower certainty value. For example, as suggested herein, a reference burst width could originally come from empirical data from many test patients experiencing actual seizures, and be a factory default. Later, as data from the patient is gathered, a more representative ideal width could be established for that patient. The rating of a burst width could be normalized to a max value of 50 and added to the SNR value for a maximum of 100. Other metrics could be factored in as well and each could be weighted differently. One example of a method of weighting would be to normalize each to a different value:

SNR	40%
Width	35%
Amplitude	25%

A similar process for establishing certainty values could be implemented for each sub-algorithm.

[0091] An equation that the supervisory algorithm could use to quantify the decision process is: $Seizure_detection = A*(Burst_Train_Flag*Certainty) + B*(Periodicity_good_flag*Certainty_good) - C*(Periodicity_bad_flag*Certainty_bad) + D(GTC_flag*Certainty_value)$

If the sum is greater than a Seizure Detection Threshold variable value, then the supervisory algorithm declares a seizure. Other seizure variables may be used, such as Seizure Length could be used to specify how long (time in seconds) the seizure must be in process before an alarm is generated. If the sum is less than a Seizure Detection Threshold variable value, then the supervisory algorithm may be inactive for a period of time before re-scanning sub-method registers.

[0092] It can be seen from the above equations that if the periodicity is good, it adds to the summation with one weight. If the periodicity is bad, it subtracts from the summation with another weight. This allows the periodicity algorithm to strongly vote against a seizure detection if it determines that the EMG signals include obvious interference such as harmonics from the power mains, fluorescent lights, etc. Other inputs such as temperature or heart rate could be added with their own coefficients and certainty values. Sometimes heart rate can be detected with EMG electrodes and thus would require no more electrodes. However, dedicated electrodes for heart rate and temperature may provide better signals with respect to those phenomena.

[0093] An aspect of systems and methods described herein is that they may be readily customized and adapted as more data regarding general seizure characteristics for a patient, or patient demographic, is collected. Such methods may use algorithms that may have a set of routines, coefficients, or other values that may be included in a modifiable template file. It may, in some embodiments, also be useful that a detection system, e.g., a system that is designed to quickly detect seizures, has an accurate log of the data and also a log of the condition of a patient. That is, for example, a detection system that has accurately logged the event it is intended to detect and the detection data itself (and correlated those events in time), may, as described below, be optimized.

[0094] To appreciate the concept of a template file and adaptive aspects of systems described herein, reference may now be made to Figs. 15 and 16. Fig. 15 shows at a high level, a method 174 of data collection. Such a method may be used to optimize the detection of seizures. In method 174 an initial template file may be generated or selected for an individual (step 176). Once a template is generated or selected it may be added to computer memory of a detection unit and/or a base station. An example of some data that may be included in a template file was shown in Table 1.

[0095] A number of approaches may be used for establishing an initial template file. In some embodiments, a patient may be monitored for a period of time in a hospital or other controlled setting and data, such as data derived from EMG electrode outputs, may be collected and correlated with the presence or absence of seizures, i.e., general seizure characteristics for an individual may be established. From that data, an operator or software may generate an initial template file or select an appropriate file from a list of pre-generated templates. In some embodiments, an initial template file may be obtained using historical data from a general patient demographic. For example, a patient may be defined by various characteristics including, for example, any combination of age, gender, ethnicity, weight, level of body fat, fat content in the arms, fat content in the legs, fitness level, or the patient may be defined by other characteristics. The patient's medical history including, for example, history of having seizures, current medications, or other factors may also be considered. Once a template file is generated or selected it may be included in computer memory within a

detection unit and base unit and an individual may use the detection unit in a home-setting.

[0096] In step 178 a patient while in a home-setting may collect and process EMG output or other detector output, such as using a detection unit. It should be noted, as indicated in Fig. 1, that a detection unit may be in communication with a base unit, transceiver and also with a data storage unit. Thus, any portion of data may be collected, processed and also sent to a data archive. In Fig. 15, the storage of detector data is illustrated in step 180. Any portion of the data, e.g., raw data or processed data may be stored. In some examples, data may be converted to a model form that allows one to access the data and determine how that data would have behaved if analyzed in another algorithm. For example, the noise value in periods between shaped data bursts may be stored as value and may not include a point by point data file that includes all fluctuations in the baseline. Bursts may themselves be shaped and this pattern may be stored. In some examples, data may be added to a storage archive and more than one different template applied to that data. That is, the data may be analyzed with any number of template files and the results of that analysis stored for future review. In that light, the results of running different pre-generated templates may be stored and not raw data or other processed data. Of course, the results of running those pre-generated templates may be evaluated and it may be determined, e.g., after comparison of those results with data reflecting the physical states of patients, that one template, i.e., a template that was not used to monitor a patient, would have in fact detected the patient's seizures in a preferred manner.

[0097] Adapting an algorithm to better detect seizures in an individual patient or patient demographic may depend not only on the organization of detector data but also upon corroborating information, e.g., for any given portion of detector data, the physical condition of the patient. That is, it may, in some examples, be useful to document, along with EMG or other detector data, a record of what actually occurred at certain points in a data stream. Such information may, for example, be identified by a caregiver, as indicated in step 182. A caregiver may also provide such information to a data storage facility, which may store the information (step 184). Alternatively, one caregiver may provide such information to an operator who may execute an optimization procedure. Information provided to data storage may include, for example, whether a suspected seizure was verified to be a seizure, whether a suspected seizure was in fact something different, the location of the patient when an incident occurred, severity of the seizure, time of the incident, any medical care that may have been issued and other information as well. At least some of this information may also be provided by the patient or individual.

[0098] In addition, in some examples, a patient may also provide information related to general seizure characteristics. For example, a patient may receive an alert from the detector unit that a seizure is in progress (step 186). An individual, if alert, and aware that they are in fact not experiencing a seizure, may be given the option of sending a message to a caregiver and/or to a data storage unit that a false positive was alerted by the system. In some examples, an individual may communicate the presence of a false detection by simultaneously pressing two buttons on an attached device, e.g., the detection unit or another unit. Of course, the requirement that an individual simultaneously press two buttons may minimize the risk that an inadvertent signal is sent. Any other suitable approach to minimize inadvertent messages may also be used. A message sent in this manner, e.g., sent to a storage facility from a patient (step 188), may include a time stamp to correlate a false positive event with the data which initiated the false positive event. Such information may be stored in a data storage facility (step 190)

[0099] An individual may, in some examples, also be given the option to provide additional information, e.g., other information that may be associated with any false positive event, or seizure incident. Such supporting information may include an activity they were engaged in or the physical location they were at when they received notification that a seizure is in progress. Also, a detector unit may, as previously described, be an input/output device, and thus, a seizure alert may be sent to a detector unit, or other unit carried or worn by a patient, from a base unit. That is, if the base unit controls initiation of an alarm, the base station may inform the detector unit (which is physically near the patient) that a seizure has been detected. In some examples, a device including means for reporting information, such as a false positive event, to a caregiver or data storage facility may be worn around the wrist or on the belt of a patient. An operator may access data in a data storage facility and organize the information 192.

[0100] A method 194 of optimizing seizure detection, and updating a template file, is shown in Fig 16. In step 196 an operator may add any new data, e.g., data collected in a home-setting for a patient, to any previously stored data for that patient, i.e., an operator may update a data file. Alternatively, an operator may add newly collected data for a patient to a body of data that is associated with a patient demographic. The system may in step 198, for example, use the initial template file (or a currently used template file for that patient), and characterize detection metrics for the system as applied to the individual's updated data file. Metrics of the system may include listing seizure events that were correctly identified, seizure events that were missed, false positives, and in some examples, a determination of the severity of an event that was considered to be a seizure. Also, for any given reported event, e.g., a seizure incident or false positive detection, the operator may, in some examples, be provided with a listing of the data in different registers at the time of the event. Such information may, for example, be recalculated (during optimization) from original signal data or from stored values. In a step 200, the operator may execute a computer program to select fields of information, e.g., weighting coefficients, thresholds, criteria, and selected processing routines, from the initial template file (or currently used template)

and vary those fields. The operator may also manually select and adjust one or more fields. The system may characterize detection metrics (step 202) while varying template fields and select new settings (step 204) for an updated template file. Of course, the updated template file may be downloaded to either or both of the detection unit and base station.

5 [0101] One aspect of methods and apparatuses described herein is that they are, in various embodiments, able to organize information between a detection unit and base station or between those units and a data archive. In addition, some examples may be used to organize the collection of portions of data that are most relevant.

10 [0102] In some examples, the rate at which data may be collected may depend upon whether or not an electrode is in a given state, such as an active state, resting state, or engaged in a polling operation. For example, Fig. 17 illustrates one example of a method 206 of detecting seizures in which the rate of data collection depends upon the state of an electrode. Method 206 may, for example, be used to toggle a detection unit and/or base station between a "sleep" mode, i.e., characterized by operations within dashed line 208, and a mode of substantially continuous operation, such as active state 214. As shown in Fig. 17, a detector and/or base unit may be configured to exist in the resting state 200 for a portion of time while in a "sleep mode." While in the resting state 210 a detector or base unit may be silent, e.g., it may not be monitoring or collecting data from a patient. The resting state may include instructions to periodically exit the resting state 210 and, for example, collect detector data for a period of time. That is, a detector may enter a polling operation step 212 where data is collected. The duration of an individual polling operation may be sufficient to collect data as needed to make a decision regarding the state of an electrode. That is, for example, based on data collected during polling step 212 a detector may revert back to the resting state 210 or may enter another state, such as active state 214.

20 [0103] Any of various routines may be used to collect data for toggling between a resting and active state. An amplitude detection algorithm may, for example, be used to switch an electrode between a resting and active state. Figure 18 illustrates one example of an amplitude detection algorithm 216. An EMG signal amplitude may be, for example, a peak value, a mean value, a median value, an integrated value, or other value that may be measured at a given time point or over a selected time interval. EMG signal amplitude may be normalized or calibrated for a patient's baseline activity. As shown in Fig. 18, in a step 218 one or more electrodes in a resting state may "wake up" and measure the EMG signal amplitude. For example, as illustrated in step 220, if the amplitude is above a threshold level, then the one or more electrodes may continue to measure the EMG signal amplitude and if the threshold level is not obtained, the one or more electrodes may return to a resting state. By having a period of time in which a detection unit is in "sleep" mode, a system may conserve battery life, minimize the amount of data that is stored in memory, minimize the amount of data that is transferred over a network, or serve other functions. In some examples, a decision to enter an active state, and monitor a patient in a more continuous manner, may be made based on factors in addition to amplitude detection.

25 [0104] Additional examples that may be used to allocate data collection among devices are shown in Figs. 19 and 20. In the example of Fig. 19, an EMG electrode in a detection unit detects an EMG signal, determines the spectral content of the signal, and may compare the spectral content to a model GTC waveform stored in the detection unit's memory. If the spectral content is substantially similar to the GTC waveform, then the detector unit may send approximately ten seconds-worth of EMG signal to the base station. Preferably, the sent EMG signal includes the signal that formed the basis of the comparison. The base station may independently determine the spectral content of the received signal, and compare the spectral content to the GTC waveform stored at the base station. If the spectral content is substantially similar to the GTC waveform, then the base station may send an alert to a remote station or caregiver. Thus, in one example, for an alert to be sent, both the detection unit and base station must each determine that the spectral content of the EMG signal is substantially similar to the GTC waveform.

30 [0105] In the example of Fig. 20, an EMG electrode in a detection unit detects an EMG signal, determines the spectral content of the signal, and compares the spectral content to the GTC waveform stored in the detection unit. If the spectral content is substantially similar to the GTC waveform, then the detector unit may send approximately ten seconds-worth of EMG signal to the base station. Preferably, the sent EMG signal includes the signal that formed the basis of the comparison. The base station may independently determine the spectral content of the received signal, and compare the spectral content to the GTC waveform stored at the base station. The base station may also analyze the received signal for burst activity, as described above, such as regular periodicity, to determine if burst thresholds are met. If the spectral content is substantially similar to the GTC waveform, and the base station recognizes burst activity that meets the burst thresholds, then the base station may send an alert to a remote station or caregiver.

35 [0106] Similarly, processing of EMG signal data for various seizure variable values may be accomplished at the detection unit, at the base station, or both, depending on processor existence and capability, and storage capacity.

40 [0107] Some additional processing techniques that may be used in the above algorithms or in other sub-methods are described below. For example, a register may be populated in a manner such the level, or value of the contents, of the register is related to the time that a seizure variable may be above threshold, related to the magnitude of a certain characteristic of data, e.g., seizure variable, or both. For example, a register may be loaded with a set numerical value every X seconds that a certain characteristic is maintained above a threshold. Thus, if a given number of time periods, e.g., nX seconds, are maintained with the characteristic above threshold, the method may advocate a seizure detection.

If the characteristic drops below threshold, the register may be reset or decremented in some manner. In such an embodiment, an alarm may be triggered based on the number of time periods that a certain characteristic is above threshold. A register (e.g., a first register) may also be loaded with a numerical value every X seconds that a certain characteristic is above a threshold, and that numerical value may be proportional to the magnitude of signal or number of events detected over the provided time period. At the completion of every X seconds, a second register may be populated in a manner that depends upon the first register, e.g., whether it is maintained above a certain level. In such an embodiment, an alarm may be triggered, for example, if the second register is populated for a certain number of consecutive time periods. The first register may, in some embodiments decrement at a certain rate. For example, the first register may be loaded every X seconds in a manner proportional to the magnitude or number of registered events and also decremented each X second period. Thus, the first register may either increase in value or decrease in value as dependent upon how it is incremented or decremented. In some embodiments, an alarm may be triggered if either the second register exceeds a certain threshold, if the first register exceeds threshold, or if either or both exceeds a certain threshold. If a characteristic evaluated is of a type where an integration calculation is needed, then the method may increment the register a specific amount every X seconds. If the register is set to decay more slowly than the rate of increment, then the register value will increase over time. A slower rate of increase may allow the method to slowly build up to a higher confidence level of seizure detection.

[0108] In some examples, an EMG electrode in a detection unit may detect an EMG signal, determine the spectral content of the signal, and compare the spectral content to the GTC waveform stored in the detection unit. If the spectral content is substantially similar to the GTC waveform, then the detector unit may send an alert to the base station, a remote station, and/or caregiver. The detector unit may send the alert without requiring corroborative analysis by the base station. In yet other examples, the detector unit may further analyze the EMG signal for seizure burst activity, as described above, such as regular periodicity, to determine if burst thresholds are met. If the spectral content is substantially similar to the GTC waveform, and the detector unit recognizes burst activity that meets the burst thresholds, then the detector unit may send an alert to a base station, a remote station and/or caregiver.

[0109] In some examples, the seizure detection system may be provided with a generalized GTC waveform and calibrated for a patient's baseline activity, e.g., sleeping, daytime activity, etc. When waveform activity increases, the seizure detection system may compare the signals collected by the detection unit to the generalized GTC waveform. The seizure detection system may begin to characterize the signals and look for elevated signal amplitudes. The seizure detection system may process the signals to generate spectral content by well understood methods such as Fast-Fourier Transform (FFT). The seizure detection system may apply filtering to more clearly reveal higher-frequency "bursts." The seizure detection system may determine if the processed signal fits the generalized seizure characteristics by measuring one or more of the factors of amplitude, count, time length of train, and periodicity of bursts and comparing those factors against stored patterns and thresholds. If the thresholds are exceeded, then an alarm may be sent, e.g., to the base station together with data. The base station may separately process the data for verification of the alarm condition. If the base station agrees with the alarm, then the base station may generate an alarm to remote devices and local sound generators. An alarm may comprise an audible signal, or a text message, or email, or trigger vibration in a PDA, or other suitable attention-getting mechanisms. In some embodiments, having the base station agree to the detection unit's alarm introduces a voting mechanism for reducing false alarms. Both devices must vote on the decision and agree to sound the alarm. This may be used to limit false alarms. Of course, a processor in a patient-mounted unit may process the EMG signals based on burst detection, and may separately process the EMG signals based on GTC waveform, and may send an alert if both processes indicate that an alarm protocol should be initiated. Thus, voting may occur within a device, as well.

[0110] In some examples, during or after a seizure event, a human operator may review and adjust thresholds based upon the severity of the seizure or possibly the non-detection of an actual seizure because of high thresholds. Many people have seizures and do not realize that they had a seizure, e.g., the short-lived seizures discussed above. Having this data to review may help medically manage the person with seizures. Also, a human operator may evaluate the data and conclude that a seizure did not occur, and either cancel the alarm or instruct the seizure detection system that the detected waveform did not indicate a seizure. Likewise, a human operator may instruct the seizure detection system that an undetected seizure had occurred by, e.g., specifying the time during which the seizure occurred. For example, the graphs in the figures discussed above may comprise a rolling "window" of EMG activity, and the human operator may "rewind" the recorded signal and indicate to the seizure detection system the time window in which the seizure occurred. In some examples, the base unit may include a visual display that allows display of EMG signals in time and spectral domain to allow a caregiver to view historical seizure data. In some examples, the base station may visually depict the signal and provide a graphic user interface (GUI) that allows human operators to accomplish the "window" selection and define other operating thresholds and conditions. For example, the system 10 of Fig. 1 may include a video camera that records the patient while sleeping to allow a caregiver to review the EMG signal in coordination with video footage to assess a patient's condition corresponding that EMG signal. Thus, video data may be stored along with EMG signal data, and reviewed, for example, on the base station GUI along with the EMG signal graphs. In other words,

the base station could allow a caregiver to view EMG signal graphs and corresponding video data side-by-side. The seizure detection system may thus have additional data points against which to evaluate future seizure events for that particular patient. The seizure detection system may employ adaptively intelligent software to "learn" the patient's seizure patterns, and over time effectively customize the generalized GTC waveform to better detect seizures in that patient.

[0111] An apparatus for detecting seizures is preferably man-portable, and may include a detection unit that may be attached to the body, such as by use of an elastic arm band. The detection unit may be battery powered, and may wirelessly communicate with the base station. The detection unit may include sufficient data storage, processing and transmission capability to receive, buffer, process and transmit signals. The detection unit may process the signals and conduct a simplified comparison, e.g., using two factors of amplitude and frequency, with the generalized seizure detection requirements stored in the detection unit. When the detection unit determines that a seizure is occurring, it can download both its analysis and the raw signal data to a bedside base station for more complex processing. The base station may have much more power, larger storage capability and greater processing speed and power, and be better able overall to process the information. It could have a larger database of patterns to compare against. As the seizure detection system "learns" the patient's patterns, the base station may modify the generalized seizure detection requirements to more closely model the patient's pattern. The base station may update the detection device periodically with the modified generalized seizure detection requirements. Likewise, the base station may transmit raw and processed signal data to a remote computer for further analysis and aggregation with signal data from other units in use. For example, multiple base stations may transmit data for multiple patients to a remote computer. Each base station may not receive the other base station's data, but the remote computer may serve as a common repository for data. Aggregation of the data may allow further data points upon which to further refine the generalized seizure detection requirements, thresholds and statistical information that may be supplied to base stations and detection units as a factory default.

[0112] As previously noted, in some examples, in addition to using EMG, electrocardiography (ECG) may be used to corroborate (or contradict) the occurrence of a seizure. This option could be used with particularly difficult patients. Patients with an excessive amount of loose skin or high concentrations of adipose tissue may be particularly difficult to monitor. For example, a factor associated with reliable EMG measurements, is the stability of the contact between the electrodes and skin. For some patients this may be difficult to achieve in a reliable manner. ECG data may be included in a method for determining a likelihood of whether a seizure related incident is taking place (or has taken place) and ECG data may be used to determine whether a seizure should be declared, e.g., an alarm initiated. Moreover, skin and fat are inherently a type of frequency filter.

[0113] Heart rate may, for example, elevate during a seizure, e.g., a patient may become tachycardic. As discussed further herein, if the EMG processing portion of the seizure detection apparatus determines that a seizure may be in progress and the heart rate does not go up, then the confidence of the detection may be reduced. For example, epileptic patients that use a beta blocker drug may not experience a rise in heart rate. In such situations, a method incorporating heart rate as a factor may be provided with a coefficient to lower the weight given to that factor. Thus, the disclosed detection method and apparatus may be adjusted or readily customized according to patient-specific considerations, such as use of a particular drug regimen. In some embodiments, ECG may be used to detect other cardiac dysrhythmia, such as bradycardia or asystole following a seizure, and to send an alarm if such a condition is detected. Data from a temperature sensor situated as to detect patient temperature may also be used to corroborate occurrence of a seizure or to initiate an alarm.

[0114] Generally, the devices of a seizure detection system may be of any suitable type and configuration to accomplish one or more of the methods and goals disclosed herein. For example, a server may comprise one or more computers or programs that respond to commands or requests from one or more other computers or programs, or clients. The client devices, may comprise one or more computers or programs that issue commands or requests for service provided by one or more other computers or programs, or servers. The various devices in Fig. 1, e.g., 12, 13, 14, 16, 17, 18 and/or 19, may be servers or clients depending on their function and configuration. Servers and/or clients may variously be or reside on, for example, mainframe computers, desktop computers, PDAs, smartphones (such as Apple's iPhone™, Motorola's Atrix™ 4G, and Research In Motion's BlackBerry™ devices), tablets, netbooks, portable computers, portable media players with network communication capabilities (such as Microsoft's Zune HD™ and Apple's iPod Touch™ devices), cameras with network communication capabilities, wearable computers, and the like.

[0115] A computer may be any device capable of accepting input, processing the input according to a program, and producing output. A computer may comprise, for example, a processor, memory and network connection capability. Computers may be of a variety of classes, such as supercomputers, mainframes, workstations, microcomputers, PDAs and smartphones, according to the computer's size, speed, cost and abilities. Computers may be stationary or portable, and may be programmed for a variety of functions, such as cellular telephony, media recordation and playback, data transfer, web browsing, data processing, data query, process automation, video conferencing, artificial intelligence, and much more.

[0116] A program may comprise any sequence of instructions, such as an algorithm, whether in a form that can be

executed by a computer (object code), in a form that can be read by humans (source code), or otherwise. A program may comprise or call one or more data structures and variables. A program may be embodied in hardware or software, or a combination thereof. A program may be created using any suitable programming language, such as C, C++, Java, Perl, PHP, Ruby, SQL, and others. Computer software may comprise one or more programs and related data. Examples of computer software include system software (such as operating system software, device drivers and utilities), middle-ware (such as web servers, data access software and enterprise messaging software), application software (such as databases, video games and media players), firmware (such as device specific software installed on calculators, key-boards and mobile phones), and programming tools (such as debuggers, compilers and text editors).

[0117] Memory may comprise any computer-readable medium in which information can be temporarily or permanently stored and retrieved. Examples of memory include various types of RAM and ROM, such as SRAM, DRAM, Z-RAM, flash, optical disks, magnetic tape, punch cards, EEPROM. Memory may be virtualized, and may be provided in, or across one or more devices and/or geographic locations, such as RAID technology.

[0118] An I/O device may comprise any hardware that can be used to provide information to and/or receive information from a computer. Exemplary I/O devices include disk drives, keyboards, video display screens, mouse pointers, printers, card readers, scanners (such as barcode, fingerprint, iris, QR code, and other types of scanners), RFID devices, tape drives, touch screens, cameras, movement sensors, network cards, storage devices, microphones, audio speakers, styli and transducers, and associated interfaces and drivers.

[0119] A network may comprise a cellular network, the Internet, intranet, local area network (LAN), wide area network (WAN), Metropolitan Area Network (MAN), other types of area networks, cable television network, satellite network, telephone network, public networks, private networks, wired or wireless networks, virtual, switched, routed, fully connected, and any combination and subnetwork thereof. The network may use a variety of network devices, such as routers, bridges, switches, hubs, repeaters, converters, receivers, proxies, firewalls, translators and the like. Network connections may be wired or wireless, and may use multiplexers, network interface cards, modems, ISDN terminal adapters, line drivers, and the like. The network may comprise any suitable topology, such as point-to-point, bus, star, tree, mesh, ring and any combination or hybrid thereof.

[0120] Wireless technology may take many forms such as person-to-person wireless, person-to-stationary receiving device, person-to-a-remote alerting device using one or more of the available wireless technology such as ISM band devices, WiFi, Bluetooth, cell phone SMS, cellular (CDMA2000, WCDMA, etc.), WiMAX, WLAN, and the like.

[0121] Communication in and among computers, I/O devices and network devices may be accomplished using a variety of protocols. Protocols may include, for example, signaling, error detection and correction, data formatting and address mapping. For example, protocols may be provided according to the seven-layer Open Systems Interconnection model (OSI model), or the TCP/IP model.

[0122] Although the foregoing specific details describe certain embodiments of the invention and examples, persons reasonably skilled in the art will recognize that various changes may be made. The invention is set out in the claims.

[0123] Additional information related to the methods and apparatus herein described may be understood in connection with the examples provided below.

EXAMPLES:

Example 1

[0124] In one example, a patient who may be susceptible to having seizures may be monitored. The patient may, for example, be monitored during a period immediately following a hospitalization, or at some other time where they are at risk for SUDEP. It may be useful to set up the monitoring protocol for the patient, based at least in part, upon data obtained for the patient while the patient is monitored for seizures in a controlled setting. For example, during hospitalization the patient may be monitored and data may be collected for determining general seizure characteristics. The patient may, for example, be monitored with EMG over a period of several days, or some other interval, as necessary to collect data associated with a statistically significant number of seizures. During the period of hospitalization, the patient EMG data may be collected by placing bipolar differential electrodes on or near one or more pairs of muscles, e.g., agonist and antagonist muscle pairs. EMG data may, for example, be collected from a first group of muscles, e.g., the biceps and triceps, and a second group of muscles, e.g., the hamstrings and quadriceps. EMG data from time periods with known seizures and also intervals with non-seizure periods may be collected, archived and an operator may analyze the data.

[0125] An operator may analyze the data and characterize how the patient data relates to a seizure variable, including, for example, seizure variables characteristic of a burst. An operator may, for example, measure the amplitude, width, and determine the signal to noise (S/N) ratio for portions of data that are elevated, i.e., periods that may be characterized as data bursts. Signal to noise calculations may involve, establishing a baseline by determining fluctuations in detector signal, i.e., baseline noise, in a time period immediately prior to data in a time suspected of containing bursts. Various

filters may be applied to the data, e.g., digitized data may be subjected to a 3rd order Butterworth filter from 300 Hz to 500 Hz or filtered in another manner. Using data that is filtered, the operator may, for example, repeat measurement of amplitude, width, and signal to noise (S/N) ratio for data at times that appears to contain data bursts. The operator may then select threshold values associated with burst measurements. Alternatively, an operator may opt to use threshold values typical for all patients or patients of a certain demographic.

[0126] Similarly, an operator may, for example, determine the frequency position of local minimum values and local maximum values of power density for the spectral data. For example, data from a certain time window, such as five seconds, may be collected and converted to spectral data (in the frequency domain). The operator may determine local maximum and minimum values and specify a range of frequencies on either side of the local maximum value and local minimum value and an algorithm may calculate the area under the power density/frequency curves. The ratio of these areas may be used as the value of a seizure variable, e.g., a slump to bump ratio. A threshold value for the slump to bump ratio may be specified by the operator or selected from a template file for all patients, or patients of a certain demographic.

[0127] An operator may import archived data, i.e., data from periods collected in which a seizure was present and other non-seizure periods, into a computer program using the selected threshold values and instructions for executing an algorithm. The algorithm may, for a given time window, e.g., 5 seconds, calculate values of burst related seizure variables. For example, for any time period, software may detect possible bursts, and may also measure amplitude, width and S/N. If bursts meet the criteria established, e.g., are within the set thresholds, the computer may populate a value in a burst detection register. To clarify the flow of data in the algorithm, model data from Example 1 may be referenced to Fig. 21. Fig. 21 shows how model data in a procedure (270) for analysis of data bursts may be organized, and how data may be transferred between a detection register in computer memory and an accumulation register, also in computer memory. In a first interval of time (271), data may be analyzed, and for example, it may be determined that three events meet threshold requirements for characterization as bursts. In a step (272) data may be transferred to a detection register. The detection register (273) in Fig. 21 is represented by dashed line (273), and the flow of information within the detection register (273) is represented by blocks (274, 275, 277, and 278), which represent the detection register (273) in different states. As data is transferred in step (272), the detection register in a state (274), i.e., storing a data value of zero, may become populated with a value of three, as shown in state (275). In a step (279), the data value stored in the detect register (273) may be transferred to an accumulation register (280). In Fig. 21 the burst train accumulation register (280) is represented by dashed line (280), and the flow of information within the burst train accumulation register (280) is represented by blocks (281, 282, 284, and 285), which represent the accumulation register in different states. In step (279), the accumulation register in a state (281), i.e., a store storing a data value of zero, may become populated with a value of three, as reflected in state (282). Referring back to the detection register (273), upon transferring contents to the accumulation register (280), in step (276), the detection register (273) may clear its contents, as reflected in state (277). As reflected in step (286), in a second interval of time (286), another interval of data may be analyzed, and for example, it may be determined that five events meet threshold requirements and are characterized as bursts. In step (287), the detect register (273), now in state (277) may receive data associated with the measured burst value from step (287), i.e., a value of five. The detect register (273) may now hold a data value of five, as shown by state (278). Prior to transfer of data from the detect register, i.e., in state (278) to the burst train accumulation register (280), the burst train accumulation register (280), may be subjected to an adjust accumulation register step (283). That is, in step (283) the burst train accumulation register may be adjusted in value. For example, as illustrated in Example 1, the accumulation register is shown to "leak" a value of one during the adjust accumulation register step (283). Thus, if step 283 denotes a leakage value of one and if a greater number of bursts are detected in successive time intervals, e.g., steps (271) and (286), then the accumulation register will increase in value. For example, as shown in Example 1, in step (288), the detect register (273) transfers its contents to the burst train accumulation register (280), while the burst train accumulation register is in state (284), and a value content of five is transferred to the burst train accumulation register (280). The accumulation register would then hold a data value of seven, as shown for state (285).

[0128] In addition to the steps above, an algorithm may also involve other registers, e.g., a GTC accumulation register. For example, as described in relation to Fig. 22, a GTC accumulation register (290) may be populated. Thus, it should be appreciated that at any point in time, the burst train accumulation register (280) and the GTC accumulation register (290) may hold a value. A supervisory algorithm (162), may be used to analyze the data in those registers (285) and (290). To clarify the flow of data in Example 1, reference is now made to Fig. 22, as well as the general description of supervisory algorithms in Fig. 14.

[0129] As shown in Fig. 22, and using illustrative data for this Example 1, the GTC accumulation register (290) is shown to have a value of five. The burst train accumulation detection register (280) is shown to be in a state (285), and as noted previously, holds a value of seven. In a step 291 of the supervisory algorithm, the values of the registers are multiplied by a coefficient. That coefficient may be pulled from a template file and used as a weighting factor for associated seizure variables. That is, as shown in Example 1, a GTC weighting coefficient (298) may be 1.5 and a burst coefficient (299) may have a value of 1.0. The, weighted value of the two seizure variables following multiplication with their

associated coefficients may then be 7.5 (292) and 7 (293). In a step (294) those values may be added together, and as shown in Figure 22, a sum value, e.g., 14.5, may become associated with a supervisory register (295). In a step (296) the value of held in the supervisory register (295) may be compared to a threshold value. For example, a threshold value for reporting a seizure may be 14, and thus, an alarm protocol would be triggered

5 **[0130]** In Example 1, the data that is input into the algorithm is historical data from a patient's time in the hospital. Thus, the operator may in step (297) compare the results determined by the algorithm to the actual state of the patient at the time that the data was collected. That is, an operator may compare the result that would have been initiated with the actual course that was appropriate. An operator may thus compare, for all of the data that is available, how accurately the algorithm detects actual seizures and whether the algorithm would have detected any false positives, e.g., decisions to declare an alarm when the proper course of action was to not report a seizure incident.

10 **[0131]** The computer program may allow the operator to manually adjust coefficients, including for example threshold values for burst or GTC waveform detection (such as slump to bump), GTC coefficient (298), burst coefficient (299), or combinations thereof. The program may be set to automatically adjust any combination of the aforementioned coefficients in an optimization routine, wherein the computer may modify the coefficients and look for an ideal combination that provides both accurately detects seizures and also minimizes false positive detections.

15 **[0132]** The patient in Example 1 may be sent home and monitored with a configuration of EMG electrodes that closely resembles the configuration of EMG electrodes used to optimize the detection algorithm. As the patient is monitored, data may be collected and the presence of any detected seizures, missed seizures (if present), and false positives may be reported. The system may periodically analyze the available archived data, including any archived data derived while the patient is at home, and reoptimize a combination of coefficients. Thus, the system may adapt to better monitor a given patient over time.

Example 2

25 **[0133]** In this Example 2, a patient may be set up to be monitored in a home setting using a pair of EMG electrodes on the biceps and triceps. The patient may be set up to be monitored based on a template file for patients that share a demographic with the patient. In Example 2, the patient may be an obese male and an initial set of coefficients and thresholds may be used to monitor the patient based on a set of coefficients and thresholds optimized for the entire set of data from all obese males for which data is available. As distinguished, from Example 1, the patient in this example may be monitored without previous evaluation in a hospital setting. That is, the patient may be monitored with weighting coefficients derived entirely by importing values associated with other patients, e.g., patients that share characteristics with the patient. The patient in Example 2 may be monitored for several weeks and the system may record electrode data. For the model data in Example 2, the system may accurately detect five seizure events but miss one seizure event. The system may then be optimized with archived data from the patient. That is, data from the patient may be used to adjust coefficients to improve the accuracy of detecting all events.

Example 3:

40 **[0134]** In Fig. 23, the top trace labeled "EMG1-raw" shows EMG electrical activity using a bipolar EMG electrode arrangement. The trace labeled "EMG2-raw" is from a similar bipolar electrode arrangement (differential electrode) on the triceps of the same arm. The vertical scale in the Fig. 23 graphs, EMG1-raw and EMG2-raw, is signal amplitude, e.g., the differential signal between either the pair of EMG electrode inputs on the biceps or the differential signal between the pair of EMG electrode inputs on the triceps, and the horizontal scale shows time (in Fig. 23, the time window is approximately 4h28'55" to approximately 4h29'00"). Fig. 23 shows the collection of 5 seconds worth of patient data. In some embodiments, data may be collected over some other time period. Attachment of EMG electrodes on opposing muscle groups, e.g., such as the biceps and triceps, may be beneficial for several reasons. For example, as further discussed below, an electrode configuration that involves opposing muscles may be useful in the interpretation of data wherein a patient is involved in certain activities, e.g., non-seizure motion, and differentiation of data collected while the patient is engaged in such activity from electrode data collected while the patient is experiencing a seizure.

50 **[0135]** Still referring to Fig. 23, the bottom left graph (labeled "EMG1 Spectral Analysis") is a representation of the frequencies of data collected from the EMG electrode over the biceps (spectral content). The bottom right graph (labeled "EMG2 Spectral Analysis") is a representation of the frequencies of the triceps EMG electrode. Data collected over a given time period, i.e., time domain electrode data, may be converted to frequency data, i.e., spectral content, using techniques such as Fast-Fourier Transform (FFT). For the spectral data, the horizontal scale is signal frequency, and the vertical scale is the signal amplitude, which for the spectral data described herein may be referred to as the spectral density. Note that the spectral data in Fig. 23 indicates a curving slope with decreasing amplitude as the frequency increases, i.e., the spectral density generally decreases as the frequency increases. The ratio of spectral density at low frequencies to the spectral density at higher frequencies is a seizure variable that, for any given set of electrode data,

may have an associated value. For example, for the data shown in Fig. 23 the ratio of spectral density at a frequency of about 200 Hz (298) to the spectral density at about 400 Hz (300) may have a value of about 5.0. The ratio of spectral densities at those frequencies, or at other frequencies, may be a seizure variable and the value of that seizure variable, such as derived from data in Fig. 23, may be generally characteristic of non-seizure muscle activity, such as moving in bed or moving arms. In some cases, such as in Fig. 6, where the ratio at 200 Hz to 400 Hz is lower, such a ratio may be indicative of seizure activity.

Example 4:

[0136] Fig. 24 provides a spectral graph of EMG signals at a different window of time than those of Fig. 23, namely, from approximately 4h39'30" to approximately 4h39'35" when the patient is again non-seizure moving. The spectral graph shows a high spectral density across a wide group of frequencies in the frequency band. Some normal voluntary muscle movement is a coordinated contraction of agonist and antagonistic muscles in a cooperative way to achieve a particular motion. In contrast to Fig. 23, and to illustrate the coordination of different muscle groups, in Fig. 24, the data in "EMG1-raw" and the data in "EMG2-raw" are from different electrodes associated with an agonist and antagonist muscle group, i.e., data from those muscles are superimposed upon each other. In some embodiments, the coordination of signals between electrodes on agonist and antagonist muscles may be used as a negative weighting factor for detection of a seizure. Often during seizures this coordination is lost. Instead, the muscles tend to lock up with muscles fighting each other. A good example of a scenario wherein coordination of agonist and antagonist muscles is lost may be seen in the tonic phase of a motor seizure when the biceps and triceps muscles are both stimulated. These muscles will fight each other with very high amplitude signals but the arms may not move much at all. That is, data traces from different electrodes where a phase relationship is maintained for some period of time may be evidence that an individual is not experiencing a seizure.

EXAMPLE 5:

[0137] The data shown in Figs. 25-27 are collectively indicative of how electrode data may change as patients transition from a non-seizure state to the experiencing of an actual seizure. Fig. 25 shows a relatively quiet time (from time approximately 7h20'40" to approximately 7h20'45") of EMG signals obtained during sleep just prior to a seizure. The spectral graph shows only relatively low frequency activity. The amplitude of electrode data at the far right of the time domain graph (later times), e.g., the amplitude at a point (304), is increased over data illustrated at earlier times, e.g., the amplitude at a point (302). That is, the amplitude of electrode data is increasing as the seizure approaches. In some embodiments, achieving a signal amplitude may trigger a change in state for an EMG electrode or initiate transfer of data between a detector and base unit and/or data storage unit. Changing states for detectors from sleep to active is discussed above. Achieving an amplitude at a point (304), or achieving such an amplitude with a certain frequency for data points over a certain period, e.g., such as a one second interval (306), may be used as a criteria that initiates the transfer of data between a detection unit and base unit and/or data archive.

[0138] Fig. 26 shows the EMG signals recorded during sleep at the onset of a seizure (showing time approximately 7h21'00" to approximately 7h21'05"). The two lower spectral graphs ("EMG 1 Spectral Analysis" and "EMG2 Spectral Analysis") show a minor "bump" (308) (with poor signal to noise) in the spectral display at the higher frequencies, between approximately 350-450 Hz, and a minor "slump" (310) in the spectral display at lower frequencies, between about 250-350 Hz. In brief, the data in Fig. 4 shows the beginning structure of a "GTC waveform," which is shown in Fig. 5 more clearly. However, at first, during a seizure, electrode data derived from muscles, e.g., muscles whose activity is in a process of building up, during a seizure may show the "GTC waveform" only poorly (if at all), and while the spectral density is greater at higher frequencies than typically seen for non-seizure data, such data, at the start of a seizure, may seem random or show only minor variations in spectral density across high frequency regions. Some electrical signals associated with normal voluntary muscle activity, recorded with macro-electrodes are almost entirely below 300 Hz. However, electrical frequencies recorded with macro-electrodes frequently extend above 300 Hz in a sustained manner during a seizure with motor manifestations. In some embodiments, the duration of time in which a threshold spectral density is achieved, e.g., at some high frequency, may be a seizure variable.

[0139] Fig. 27 shows the evolution of the EMG signals as the seizure progresses (showing time approximately 7h21'20" to approximately 7h21'25"). As may be seen in the bottom right spectral graph, which corresponds to the triceps electrode, the characteristic GTC waveform shows a region of elevated spectral density, i.e., a relatively high-frequency "bump" between approximately 300-500 Hz, and particularly around 400 Hz. That is, the spectral density at a point (312) in that region is elevated above the spectral density (314), e.g., within a "slumped" region, approximately located within a range of about 250 Hz to 350 Hz. The ratio of spectral density at the point (312) to the spectral density at the point (314), or slump to bump ratio, may be used as a seizure variable. In comparison of the spectral graph in Figures 26 and 27 it should be noted that as the patient begins to transition into a seizure that the GTC waveform changes. For example,

a measureable slump to bump ratio becomes present in Fig. 27. As the ratio becomes measureable, a GTC detection register may become populated with an increasing value. If the GTC detection register becomes populated with a value that is greater than the leakage rate of the GTC accumulation register the value in the GTC accumulation register may increase over successive time periods.

[0140] In some examples, the slump to bump ratio may be used as a metric for detection of a GTC waveform. However, more advanced data analysis techniques, e.g., looking at a greater number of data points and/or advanced pattern recognition algorithms, may also be used to identify a GTC waveform. For example, a detection unit may include instructions for calculation of a slump to bump ratio and a base unit may calculate a slump to ratio and also corroborate the slump to bump calculation with more advanced pattern recognition analyses.

[0141] For this patient, the EMG data bursts have significant noise, i.e., large statistical fluctuations, at time points between them. Other patients may have less noise, resulting in GTC waveforms that are more clearly visible, and slump to bump ratios with greater signal to noise. A variety of analysis techniques may be used to improve the signal to noise for detection of a GTC waveform and/or slump to bump ratio. For example, spectral data over a certain frequency range may be integrated, e.g., the area of the spectral curve within a frequency range of a "bump region" may be calculated. Also, the area of the curve within a frequency range of a "slump region" may be calculated. The specific ranges for slump to bump used for integration may be optimized for a given patient. That is, historical electrode data may be accessed from a data repository, different ranges for the slump region and/or the bump region may be selected, and different values for the slump to bump calculated for each selected ranges. Some slump to bump ratios, e.g., selected with some ranges, may show better S/N ratios and/or better correlation with the presence of a seizure than a slump to bump calculated with other ranges. That is, general seizure characteristics for the slump to bump ratio using frequency data in one range may prove to be more useful, i.e., show better correlation with the presence of a seizure, than a slump to bump ratio using another frequency range. Thus, a slump to bump seizure variable may be optimized for a given patient and may be updated periodically as historical data is collected for the patient.

[0142] In some examples, data in a predetermined frequency range, e.g., a range for a patient that typically shows a slump, may be smoothed and the local minimum in the data established. The area under a curve approximately centered on the local minimum may be calculated. Similarly, the algorithm may analyze data in another predetermined frequency range, e.g., a range for a patient that typically shows a bump. Data in that range may be smoothed, a local maximum established, and the area under the curve approximately centered on the local maximum may be calculated. The area under the local minimum, area under the local maximum, and ratio of those integrals may be used as seizure variables. In some examples, a detector unit may perform a calculation of the slump to bump ratio for a given portion of electrode data and a base station may perform more advanced pattern recognition techniques on the electrode data.

EXAMPLE 6:

[0143] In Example 6, and associated Figs. 28-31, some aspects of data filtering are described. Fig. 28 illustrates additional EMG data for the same patient also during a seizure. In this embodiment, the EMG 2 signal at time approximately 7h22'50" to approximately 7h22'55" has been filtered with a 3rd order Butterworth filter from 300 Hz to 500 Hz. When filtering is applied to the EMG 2 signal, the time domain data shows a series of bursts, i.e., regions of elevated EMG signal amplitude separated by lower amplitude signals, with high signal to noise. For example, at least four different burst regions (316, 318, 320, and 322) may be detected in the data of Fig. 28. The bursts shown in Fig. 28 may be categorized based upon the number of bursts, e.g., such as four, within a time window, the period between adjacent bursts (324, 326, and 328) and the time duration of a burst (330). Such burst features may be seizure variables. Referring now to the spectral graphs in Fig. 28, application of a high frequency filter in this embodiment, clearly illustrates the presence of high intensity frequency data. Fig. 28 also shows sharp, brief frequency "spikes" in the bottom two graphs. Those spikes may generally correspond to noise from overhead lighting at household frequency of 60 Hz, and may generally appear at 60 Hz harmonics. Such interferences may be recognized and an algorithm may include instructions to disregard such data signatures. Also, the EMG1 signal (biceps) shows sustained contraction (tonic activity), and the EMG2 signal (triceps) shows periodic contraction (clonic activity). Thus, and in contrast to the data illustrated in Fig. 27, such agonist and antagonist muscle groups do not necessarily have a correlated phase between them.

[0144] The lower right graph of Fig. 29 in particular shows even more dramatically how filtering from 350 Hz to 450 Hz, in the EMG 2 signal, can reveal bursts (332, 334, and 336) and high frequency information (338) out of the electrode signal (showing time approximately 7h22'10" to approximately 7h22'15"). The selection of a given filter may in some embodiments be adjusted for a given patient.

[0145] Fig. 30 shows the exact same frame as Fig. 29, except the EMG 2 signal is unfiltered. It is evident from the spectral display that the lower frequencies have a higher amplitude as compared to the data in Fig. 29. Furthermore, bursts associated with the time domain data clearly have much lower signal to noise ratios. Based on the data in Fig. 29 and Fig. 30, it should be appreciated that electrode data may be filtered in any of various ways. The value of a given seizure variable may be determined from data collected using a filter that improves the signal to noise of the calculated

value. For example, burst width and burst count may be collected from an electrode that uses a filter, such as a 3rd order Butterworth filter from 300 Hz to 500 Hz (Fig. 28) or a filter from 350 Hz to 450 Hz (Fig. 29). Other seizure variables, such as the slump to bump ratio of a GTC waveform may be collected without use of a filter or with another filter, such as one that passes a lower range of frequencies, as shown in Fig. 30. As shown in Fig. 30 a slump region (340) and a bump region (342) may be detected.

[0146] Fig. 31 provides another good example of increasing the discrimination of seizure bursts for the EMG 2 signal with respect to the noise (time approximately 7h25'22" to approximately 7h25'27"), e.g., increasing the signal to noise ratio of the spectral data by filtering the raw data. For example, representative burst (344) shows a high signal to noise ratio. Note the relative irregularity of the bursts (344, 346, and 348), as shown in the time domain data, which may be a factor that tends to indicate a seizure. That is, the periods between adjacent bursts, such as burst interval (350) and burst interval (352), have different values. In Fig. 31 the EMG 1 data, which has not been filtered, shows a characteristic GTC waveform, with a detectable slump (354) and bump (356).

EXAMPLE 7:

[0147] In Example 7, and associated Figs. 32-34, some aspects of data that may, for example, include features that may apply negative weighting to detection algorithm are discussed. Fig. 32 may indicate a short-lived seizure preceding the foregoing seizure (time approximately 5h17'41" to approximately 5h17'46"). Several bursts (358, 360, and 362) appear to have occurred, and are evident in both the EMG 1 and EMG 2 signals. Those bursts may be of relatively low concern due to their short duration. Some patients experience many of these short seizures. Comparison, of such short bursts with archived data, e.g., historical data for such patients, may be used to modify, e.g., a minimum burst detection width criteria. Thus, the algorithm may adapt to selectively neglect some data features, i.e., short and inconsequential bursts, and the algorithm may become better adapted to avoid initiation of unnecessary alarms.

[0148] Fig. 33 provides an example of high amplitude signals even after the EMG 2 signal has been filtered (time approximately 5h15'46 to approximately 5h15'51"). As the upper two waveforms show ("EMG1-raw" and "EMG2-raw"), the signals are highly uniform, a characteristic that may be detected and may be used to assess that the data may not indicate a seizure. The bursts are also very close together (the burst period is too small). Such a characteristic may also be detected and used to qualify the data and weigh against a determination that a seizure may be occurring. In some embodiments, either the signal uniformity or time period between regions of elevated amplitude may be used to disqualify data events or may be used to apply a negative weight to a seizure variable, e.g., amplitude bursts. Data that is highly uniform or has too short a period between data events may indicate an interfering signal, such as from a nearby electrical device. In real seizures, huge spikes at several discrete frequencies are rare or nonexistent. Again, historical data may be collected for a patient and analyzed. Coefficients may be adjusted to adapt the algorithm and avoid initiation of unnecessary alarms.

[0149] Fig. 34 (time approximately 4h39'36" to approximately 4h39'40") provides another example of sustained signals that may not trigger an alarm because they are too uniform and/or have too short a period between repeating data events. Such characteristics may be attributed to external noise and are typically not associated with a seizure.

Example 8:

[0150] In example 8, and associated figures 35 and 36, data from another patient who exhibits data bursts is shown. Here, as well, a differential bipolar electrode with two inputs was placed over the person's biceps (graph not shown), and also over the persons triceps (upper graph labeled "EMG2-raw"). The vertical scale shows the amplitude of the signal. The middle graph (labeled "EMG2 filtered 350-450") shows the signal of the upper graph filtered to show 350-450Hz frequencies. Note how well defined the bursts are, e.g., representative bursts (364) and (366), and how well the 350-450 Hz filtering works to reveal the characteristic GTC waveform, as seen in the middle graph and in the lower right graph (labeled "EMG2 Spectral Analysis"). The period of the bursts is fairly regular but not the same from burst to burst. In that light, it should be appreciated that while some seizures show fairly regular periodicity, real seizures are subject to fluctuations that are greater than some sources of noise, e.g., from man-made sources or from voluntary muscle activity. The balance between near perfect regularity for an artificial source of noise and the periodicity of burst trains may be balanced for an individual patient, such as by varying coefficients and threshold variables in a periodicity algorithm.

[0151] Fig. 36 continues the waveform of this patient, and shows how well ordered, but not completely uniform, a series of bursts (368, 370, and 372) may be. This pattern may be typical for some patients and may provide a very characteristic pattern that may be assigned very high weight in an algorithm.

[0152] Although the disclosed method and apparatus and their advantages have been described in detail, it should be understood that various changes, substitutions and alterations can be made herein without departing from the invention as defined by the appended claims.

Claims

1. An apparatus (10) for detecting seizures with motor manifestations, the apparatus comprising:

5 one or more EMG electrodes (20) capable of providing an EMG signal substantially representing seizure-related muscle activity;
a processor (26; 30) configured to receive the EMG signal, process the EMG signal to determine whether a seizure may be occurring, and generate (172) an alert if a seizure is determined to be occurring based on the EMG signal;
10 said processor being configured to detect bursts of EMG signal data, assign certainty values to individual burst members among said detected bursts, and weight the number of said detected bursts as a function of the certainty value assigned to said individual burst members;
wherein said certainty values are determined based on a comparison of said individual burst members to a reference burst in terms of one or more burst characteristics selected from the group of characteristics including
15 burst signal-to-noise ratio, burst width and burst amplitude;
said processor being further configured to periodically scan a buffer in computer memory and identify the presence of a plurality of bursts over a time window, and determine the periodicity of burst characteristics over said time window; and
said processor further configured to combine (168) said burst count contribution and said periodicity contribution
20 using a supervisory algorithm (162) to determine a seizure detection value based on the certainty value weighted number of detected bursts and the periodicity of the burst characteristics, and compare (170) said seizure detection value to a threshold seizure detection value suitable to indicate if said seizure is occurring.

- 25 2. The apparatus of claim 1 further comprising one or more of an ECG electrode, a temperature sensor or an accelerometer.

3. The apparatus of claim 1, wherein the one or more EMG electrodes are mounted to one or more of an arm band, adhesive tape, or item of clothing so as to allow positioning of the one or more EMG electrodes over a muscle.

- 30 4. The apparatus of claim 1, wherein the one or more EMG electrodes are differential bipolar electrodes.

5. The apparatus of claim 1 comprising two EMG electrodes configured to be associated with an agonist/antagonist muscle pair, wherein one EMG electrode is configured to be associated with an agonist muscle, and the other EMG electrode is configured to be associated with its antagonist muscle.

- 35 6. The apparatus of claim 5 wherein the two EMG electrodes are configured to be associated with the triceps brachii and biceps brachii.

7. The apparatus of claim 1, further comprising a transceiver for transmitting the alert.

- 40 8. The apparatus of claim 1, further comprising a base station in communication with the processor for receiving the alert.

9. The apparatus of claim 8, wherein the base station further comprises an I/O device capable of allowing manual adjustment of alert settings and visually displaying the EMG signal or data based thereon.

- 45 10. The apparatus of claim 1, wherein said processor is configured to compare said bursts against a minimum threshold duration and a maximum threshold duration.

- 50 11. The apparatus of claim 1, wherein the processor is further configured to calculate an average deviation for times between bursts included among said plurality of bursts and identify if said average deviation is less than or greater than a threshold average deviation.

- 55 12. The apparatus of claim 11, wherein said supervisory algorithm is further configured to negatively weight against seizure detection if said average deviation is less than a threshold average deviation.

13. The apparatus of claim 1, wherein the processor is further configured to eliminate burst from said plurality of bursts if the bursts among said plurality are too close together or too far apart; and wherein the processor further compares the periodicity of burst characteristics over said time window to a minimum

uniformity threshold and a maximum uniformity threshold.

14. The apparatus of claim 1, further comprising one or more leads-off detectors configured to indicate whether one or more of the EMG electrodes is sufficiently close to a muscle to provide a substantially accurate EMG signal representing activity of the muscle.

15. The apparatus of claim 1, wherein the one or more EMG electrodes and processor are packaged as a single unit mountable to a human body.

Patentansprüche

1. Vorrichtung (10) zum Erfassen von Anfällen mit motorischen Manifestationen, wobei die Vorrichtung Folgendes umfasst:

eine oder mehrere EMG-Elektroden (20), die in der Lage sind, ein EMG-Signal zu liefern, das im Wesentlichen eine epilepsiebezogene Muskelaktivität darstellt;

einen Prozessor (26; 30), der für Folgendes konfiguriert ist: Empfangen des EMG-Signals, Verarbeiten des EMG-Signals um zu bestimmen, ob ein Anfall auftreten kann, und Erzeugen (172) eines Alarms, wenn bestimmt wird, dass ein Anfall basierend auf dem EMG-Signal auftritt;

wobei der Prozessor dafür konfiguriert ist, Bursts von EMG-Signaldaten zu erfassen, Sicherheitsgewichte einzelnen Burst-Mitgliedern unter den erfassten Bursts zuzuweisen und die Anzahl der erfassten Bursts als Funktion des Sicherheitswerts, der den einzelnen Burst-Elementen zugewiesen ist, zu gewichten;

wobei die Sicherheitswerte basierend auf einem Vergleich der einzelnen Burst-Elemente mit einem Referenz-Burst in Bezug auf eine oder mehrere Burst-Eigenschaften bestimmt werden, die aus der Gruppe von Eigenschaften ausgewählt werden, die Burst-Signal-Rausch-Verhältnis, Burst-Breite und Burst-Amplitude umfasst; wobei der Prozessor ferner dafür konfiguriert ist, periodisch einen Puffer im Computerspeicher abzutasten und das Vorhandensein einer Vielzahl von Bursts über ein Zeitfenster zu identifizieren, und die Periodizität der Burst-Eigenschaften über das Zeitfenster zu bestimmen; und

wobei der Prozessor ferner dafür konfiguriert ist, den Burst-Zählbeitrag und den Periodizitätsbeitrag unter Verwendung eines Überwachungsalgorithmus (162) zu kombinieren (168), um einen Anfallserfassungswert basierend auf der sicherheitswertgewichteten Anzahl erfasster Bursts und der Periodizität der Burst-Eigenschaften zu bestimmen, und den Anfallserfassungswert mit einem Schwellenangriffserfassungswert, der geeignet ist, anzuzeigen, ob der Anfall auftritt, zu vergleichen (170).

2. Vorrichtung nach Anspruch 1, die ferner eine EKG-Elektrode, einen Temperatursensor und/oder einen Beschleunigungsmesser umfasst.

3. Vorrichtung nach Anspruch 1, wobei die eine oder mehreren EMG-Elektroden an einem Armband, einem Klebeband oder einem Kleidungsstück angebracht sind, um die Positionierung der einen oder mehreren EMG-Elektroden über einem Muskel zu ermöglichen.

4. Vorrichtung nach Anspruch 1, wobei die eine oder die mehreren EMG-Elektroden differentielle bipolare Elektroden sind.

5. Vorrichtung nach Anspruch 1, die zwei EMG-Elektroden umfasst, die dafür konfiguriert sind, einem Agonisten-/Antagonisten-Muskelpaar zugeordnet zu werden, wobei eine EMG-Elektrode dafür konfiguriert ist, einem Agonistenmuskel zugeordnet zu werden, und die andere EMG-Elektrode dafür konfiguriert ist, ihrem Antagonistenmuskel zugeordnet zu werden.

6. Vorrichtung nach Anspruch 5, wobei die zwei EMG-Elektroden dafür konfiguriert sind, dem Trizeps Brachii und Bizeps Brachii zugeordnet zu werden.

7. Vorrichtung nach Anspruch 1, die ferner einen Sendeempfänger zum Übertragen des Alarms umfasst.

8. Vorrichtung nach Anspruch 1, die ferner eine Basisstation in Kommunikation mit dem Prozessor zum Empfangen des Alarms umfasst.

9. Vorrichtung nach Anspruch 8, wobei die Basisstation ferner eine E/A-Vorrichtung umfasst, die in der Lage ist, eine manuelle Einstellung der Alarmeinstellungen zu ermöglichen und das EMG-Signal oder die darauf basierenden Daten visuell anzuzeigen.

5 10. Vorrichtung nach Anspruch 1, wobei der Prozessor dafür konfiguriert ist, die Bursts mit einer minimalen Schwellendauer und einer maximalen Schwellendauer zu vergleichen.

11. Vorrichtung nach Anspruch 1, wobei der Prozessor ferner für Folgendes konfiguriert ist: Berechnen einer durchschnittlichen Abweichung für Zeiten zwischen Bursts, die in der Vielzahl von Bursts enthalten sind, und Identifizieren, ob die durchschnittliche Abweichung kleiner oder größer als eine durchschnittliche Schwellenabweichung ist.

12. Vorrichtung nach Anspruch 11, wobei der Überwachungsalgorithmus ferner dafür konfiguriert ist, negativ gegen eine Anfallserkennung zu gewichten, wenn die durchschnittliche Abweichung kleiner als eine durchschnittliche Schwellenabweichung ist.

13. Vorrichtung nach Anspruch 1, wobei der Prozessor ferner dafür konfiguriert ist, Burst aus der Vielzahl von Bursts zu eliminieren, wenn die Bursts unter der Vielzahl zu nahe beieinander liegen oder zu weit voneinander entfernt sind; und wobei der Prozessor ferner die Periodizität von Burst-Eigenschaften über das Zeitfenster mit einer minimalen Einheitlichkeitsschwelle und einer maximalen Einheitlichkeitsschwelle vergleicht.

14. Vorrichtung nach Anspruch 1, die ferner einen oder mehrere Ableitungsdetektoren umfasst, die dafür konfiguriert sind, anzuzeigen, ob eine oder mehrere der EMG-Elektroden ausreichend nahe an einem Muskel angeordnet sind, um ein im Wesentlichen genaues EMG-Signal bereitzustellen, das die Aktivität des Muskels darstellt.

15. Vorrichtung nach Anspruch 1, wobei die eine oder die mehreren EMG-Elektroden und der Prozessor als einzelne Einheit verpackt sind, die an einem menschlichen Körper angebracht werden kann.

30 **Revendications**

1. Appareil (10) pour détecter des crises épileptiques conjointement avec des manifestations motrices, l'appareil comprenant :

35 une ou plusieurs électrodes d'EMG (20) capables de fournir un signal d'EMG représentant sensiblement une activité musculaire connexe à une crise épileptique ;
 un processeur (26 ; 30) configuré pour recevoir le signal d'EMG, traiter le signal d'EMG pour déterminer qu'une crise épileptique peut, ou ne peut pas, être en train de se produire, et générer (172) une alerte s'il est déterminé qu'une crise épileptique est en train de se produire sur la base le signal d'EMG ;
 40 ledit processeur étant configuré pour détecter des salves de données de signal d'EMG, attribuer des valeurs de certitude à des éléments de salve individuels parmi lesdites salves détectées, et pondérer le nombre desdites salves détectées en fonction de la valeur de certitude attribuée auxdits éléments de salve individuels ;
 dans lequel lesdites valeurs de certitude sont déterminées sur la base d'une comparaison desdits éléments de salve individuels à une salve de référence en termes d'une ou de plusieurs caractéristiques de salve sélectionnées parmi le groupe de caractéristiques incluant : rapport signal-bruit de salve, largeur de salve et amplitude de salve ;
 ledit processeur étant en outre configuré pour balayer périodiquement une mémoire tampon dans une mémoire d'ordinateur et identifier la présence d'une pluralité de salves durant une fenêtre de temps, et déterminer la périodicité de caractéristiques de salve durant ladite fenêtre de temps ; et
 50 ledit processeur étant en outre configuré pour combiner (168) ladite contribution de compte de salve et ladite contribution de périodicité en utilisant un algorithme de supervision (162) pour déterminer une valeur de détection de crise épileptique sur la base du nombre pondéré de valeur de certitude de salves détectées et de la périodicité des caractéristiques de salve, et comparer (170) ladite valeur de détection de crise épileptique à une valeur de détection de crise épileptique de seuil appropriée pour indiquer si ladite crise épileptique est en train de se
 55 produire.

2. Appareil selon la revendication 1, comprenant en outre un ou plusieurs parmi : une électrode d'ECG, un capteur de température ou un accéléromètre.

EP 2 627 244 B1

3. Appareil selon la revendication 1, dans lequel la ou les électrodes d'EMG sont montées sur un ou plusieurs parmi : un brassard, une bande adhésive, ou un article vestimentaire, afin de permettre le positionnement de la ou des électrodes d'EMG sur un muscle.
- 5 4. Appareil selon la revendication 1, dans lequel la ou les électrodes d'EMG sont des électrodes bipolaires différentielles.
5. Appareil selon la revendication 1, comprenant deux électrodes d'EMG configurées pour être associées à une paire de muscles agoniste/antagoniste, dans lequel une électrode d'EMG est configurée pour être associée à un muscle agoniste, et l'autre électrode d'EMG est configurée pour être associée à son muscle antagoniste.
- 10 6. Appareil selon la revendication 5, dans lequel les deux électrodes d'EMG sont configurées pour être associées au triceps brachial et au biceps brachial.
7. Appareil selon la revendication 1, comprenant en outre un transmetteur-récepteur pour transmettre l'alerte.
- 15 8. Appareil selon la revendication 1, comprenant en outre une station de base en communication avec le processeur pour recevoir l'alerte.
9. Appareil selon la revendication 8, dans lequel la station de base comprend en outre un dispositif I/O capable de permettre un ajustement manuel de réglages d'alerte et d'afficher visuellement le signal d'EMG ou des données fondées sur celui-ci.
- 20 10. Appareil selon la revendication 1, dans lequel ledit processeur est configuré pour comparer lesdites salves à une durée de seuil minimum et une durée de seuil maximum.
- 25 11. Appareil selon la revendication 1, dans lequel le processeur est en outre configuré pour calculer un écart moyen pour des temps entre des salves incluses parmi ladite pluralité de salves et identifier si ledit écart moyen est inférieur ou supérieure à un écart moyen de seuil.
- 30 12. Appareil selon la revendication 11, dans lequel ledit algorithme de supervision est en outre configuré pour pondérer négativement par rapport à une détection de crise épileptique si ledit écart moyen est inférieur à un écart moyen de seuil.
- 35 13. Appareil selon la revendication 1, dans lequel le processeur est en outre configuré pour éliminer une salve de ladite pluralité de salves si les salves parmi ladite pluralité sont trop proches ou trop éloignées les unes des autres ; et dans lequel le processeur compare en outre la périodicité de caractéristiques de salve durant ladite fenêtre de temps à un seuil d'uniformité minimum et un seuil d'uniformité maximum.
- 40 14. Appareil selon la revendication 1, comprenant en outre un ou plusieurs détecteurs de perte de contact configurés pour indiquer qu'une ou que plusieurs des électrodes d'EMG sont, ou ne sont pas, suffisamment proches d'un muscle pour fournir un signal d'EMG sensiblement exact représentant l'activité du muscle.
- 45 15. Appareil selon la revendication 1, dans lequel la ou les électrodes d'EMG et le processeur sont combinés sous forme d'unité unique montable sur un corps humain.

摘要(译)

检测癫痫发作的方法可包括接收EMG信号并处理接收的EMG信号以确定在时间窗期间EMG信号中是否存在癫痫发作特征。用于检测具有运动表现的癫痫发作的装置可以包括一个或多个EMG电极，其能够提供基本上代表癫痫发作相关的肌肉活动的EMG信号;处理器，被配置为接收EMG信号，处理EMG信号以确定是否正在发生癫痫发作，并且如果基于EMG信号确定发生癫痫发作则生成警报。
