(57) **ABSTRACT**

The presence of a cardiac pulse in a patient is determined by evaluating fluctuations in an electrical signal that represents a measurement of the patient's transthoracic impedance. Impedance signal data obtained from the patient is analyzed for a feature indicative of the presence of a cardiac pulse. Whether a cardiac pulse is present in the patient is determined based on the feature in the impedance signal data. Electrocardiogram (ECG) data may also be obtained in time coordination with the impedance signal data. Various applications for the pulse detection of the invention include detection of PEA and prompting PEA-specific therapy, prompting defibrillation therapy and/or CPR, and prompting rescue breathing depending on detection of respiration.

PULSE DETECTION METHOD AND APPARATUS USING PATIENT IMPEDANCE

RELATED APPLICATION

[0001] This application is a divisional of U.S. patent application Ser. No. 10/013,941, filed on Dec. 6, 2001, which is hereby incorporated by reference herein.

FIELD OF THE INVENTION

[0002] The invention relates generally to the detection of cardiac activity in a patient, and more specifically, to a method and apparatus for cardiac pulse detection.

BACKGROUND OF THE INVENTION

[0003] The presence of cardiac pulse in a patient is presently detected preferably by palpating the patient's neck and sensing changes in the volume of the patient's carotid artery due to blood pumped from the patient's heart. If a pulse can be felt at the carotid artery, it is likely that the patient's heart is pumping sufficient blood to support life. A graph representative of the physical expansion and contraction of a patient's carotid artery during two consecutive pulses, or heartbeats, is shown at the top of FIG. 1. When the heart's ventricles contract during a heartbeat, a pressure wave is sent throughout the patient's peripheral circulation system. The carotid pulse shown in FIG. 1 rises with the ventricular ejection of blood at systole and peaks when the pressure wave from the heart reaches a maximum. The carotid pulse falls off again as the pressure subsides toward the end of each pulse.

[0004] An electrocardiogram (ECG) waveform describes the electrical activity of a patient's heart. The middle graph of FIG. 1 illustrates an example of an ECG waveform for two heartbeats corresponding in time with the carotid pulse. Referring to the first shown heartbeat, the portion of the ECG waveform representing depolarization of the atrial muscle fibers is referred to as the "P" wave. Depolarization of the ventricular muscle fibers is collectively represented by the "Q," "R," and "S" waves of the ECG waveform. Finally, the portion of the waveform representing repolarization of the ventricular muscle fibers is known as the "T" wave. Between heartbeats, the ECG waveform returns to an isopotential level.

[0005] Discussed herein with respect to the present invention is the correlation of fluctuations in a patient's transthoracic impedance with blood flow that occurs with each cardiac pulse wave. The bottom graph of FIG. 1 illustrates an example of a filtered impedance signal for a patient in which fluctuations in impedance correspond in time with the carotid pulse and ECG waveform.

[0006] The lack of a detectable cardiac pulse in a patient is a strong indicator of cardiac arrest. Cardiac arrest is a life-threatening medical condition in which the patient's heart fails to provide enough blood flow to support life. During cardiac arrest, the electrical activity may be disorganized (ventricular fibrillation), too rapid (ventricular tachycardia), absent (asystole), or organized at a normal or slow heart rate (pulseless electrical activity). A caregiver may apply a defibrillation shock to a patient in ventricular fibrillation (VF) or ventricular tachycardia (VT) to stop the unsynchronized or rapid electrical activity and allow a perfusing rhythm to commence. External defibrillation, in particular, is provided by

applying a strong electric pulse to the patient's heart through electrodes placed on the surface of the patient's body. If a patient lacks a detectable pulse but has an ECG rhythm of asystole or pulseless electrical activity (PEA), an appropriate therapy includes cardiopulmonary resuscitation (CPR), which causes some blood flow.

[0007] Before providing defibrillation therapy or CPR to a patient, a caregiver must first confirm that the patient is in cardiac arrest. In general, external defibrillation is suitable only for patients that are unconscious, apneic (i.e., not breathing), pulseless and in VE or VT. Medical guidelines indicate that the presence or absence of a pulse in a patient should be determined within 10 seconds. See, "American Heart Guidelines 2000 for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, Part 3: Adult Basic Life Support," *Circulation* 102 suppl. I: I-22-I-59, 2000.

[0008] Unfortunately, under the pressures of an emergency situation, it can be extremely difficult for first-responding caregivers with little or no medical training to consistently and accurately detect a cardiac pulse in a patient (e.g., by palpating the carotid artery) in a short amount of time such as 10 seconds. See, Eberle B., et al., "Checking the Carotid Pulse Diagnostic Accuracy of First Responders in Patients With and Without a Pulse" *Resuscitation* 33: 107-116, 1996. Nevertheless, because time is of the essence in treating cardiac arrest, a caregiver may rush the preliminary evaluation, incorrectly conclude that the patient has no pulse, and proceed to provide defibrillation therapy when in fact the patient has a pulse. Alternatively, a caregiver may incorrectly conclude that the patient has a pulse and erroneously withhold defibrillation therapy. A need therefore exists for a method and apparatus that quickly, accurately, and automatically determines the presence of a pulse in a patient, particularly to prompt a caregiver to provide defibrillation or CPR therapy, as appropriate, in an emergency situation.

SUMMARY OF THE INVENTION

[0009] The present invention provides a method and apparatus that determines the presence of a cardiac pulse in a patient by evaluating fluctuations in an electrical signal that represents a measurement of the patient's transthoracic impedance. By physiologically associating impedance fluctuations with the presence of a cardiac pulse, the presence or absence of a cardiac pulse in the patient is determined.

[0010] In accordance with one aspect of the present invention, impedance signal data obtained from a patient is analyzed for a feature indicative of the presence of a cardiac pulse. Whether a cardiac pulse is present in the patient is determined based on the feature in the impedance signal data.

[0011] The feature in the impedance signal data may be obtained from evaluating an amplitude of the impedance signal data, an energy in the impedance signal data, and/or a pattern match statistic resulting from comparing the impedance signal data with a previously-identified impedance signal pattern known to predict the presence of a cardiac pulse. Other determination and classification techniques known in the art may be used for the evaluation.

[0012] As to evaluating the amplitude of the impedance signal data, low and high peak amplitude values in the impedance signal data may be located and the peak-to-peak change in the amplitude from the low to the high peak amplitude

value may be calculated. The peak-to-peak change in amplitude, constituting a feature indicative of the presence of a cardiac pulse, may be compared to a threshold to determine the presence of a pulse.

[0013] As to evaluating energy in the impedance signal data, an energy calculation may be performed using impedance signal data obtained from the patient. The calculated energy, constituting feature indicative of the presence of a cardiac pulse, is compared to a predetermined threshold to determine whether a cardiac pulse is present in the patient.

[0014] As to analyzing the impedance signal data using pattern matching, the impedance signal data may be compared to a previously-identified impedance signal pattern known to predict the presence of a cardiac pulse. The comparison produces a pattern match statistic, constituting the feature indicative of the presence of a cardiac pulse, which is compared to a predetermined threshold to determine whether a cardiac pulse is present in the patient.

[0015] The impedance signal data may be obtained from the patient using defibrillation electrodes placed on the patient or using separate impedance-sensing electrodes placed on the patient. If separate electrodes are used, the present invention includes prompting application of the defibrillation electrodes to the patient if a cardiac pulse is determined not present in the patient.

[0016] In accordance with another aspect of the present invention, electrocardiogram (ECG) data is obtained from the patient in time coordination with the impedance signal data. A QRS complex located in the ECG data is used to select a segment of the impedance signal data for further analysis. If a pulse is present in the patient, the pulse should be detectable following the located QRS complexes.

[0017] In accordance with yet another aspect of the present invention, pulseless electrical activity (PEA) may be detected when the patient is determined pulseless and the patient is not experiencing ventricular defibrillation (VF), ventricular tachycardia (VT), or asystole. In circumstances where PEA is found present, the present invention includes prompting delivery of PEA-specific therapy to the patient. The present invention may be employed in a variety of devices that provide monitoring and/or therapy. If, for example, the patient is determined pulseless and experiencing VT with a pulse rate greater than 100 beats per minute, the present invention may prompt delivery of a defibrillation pulse. If a cardiac pulse is later found in the patient after delivery of the defibrillation pulse, the present invention may report the return of spontaneous circulation in the patient.

[0018] The present invention is further useful in evaluating capture while delivering pacing stimuli to a patient. If a cardiac pulse is not detected immediately following a pacing pulse, the current level of the pacing pulse may be increased until capture by the pacing stimuli is achieved.

[0019] Other applications and advantages of the present invention are readily apparent. For example, the invention may be implemented in an automated external defibrillator (AED) that prompts the user to perform cardiopulmonary resuscitation (CPR) based on the absence of a pulse in a patient. The AED may also prompt the user to provide rescue breathing depending on detection of respiration. In regard to the latter, the impedance signal data and other relevant infor-

mation, such as the patient's ECG, may be analyzed to detect the presence of respiration in the patient.

[0020] Embodiments of the invention intended for trained medical personnel may provide a display of the impedance signal data that is representative of the presence or absence of a pulse in a patient. In that regard, the impedance signal data may be shown as a way form, as shown in FIG. 1. The impedance signal data may also be displayed as a bar.

BRIEF DESCRIPTION OF THE DRAWINGS

[0021] The foregoing aspects and many of the attendant advantages of this invention will become more readily appreciated as the same become better understood by reference to the following detailed description, when taken in conjunction with the accompanying drawings, wherein:

[0022] FIG. 1 is a pictorial diagram of a carotid pulse waveform, an electrocardiogram (ECG) waveform, and a filtered transthoracic impedance signal for two consecutive heartbeats reflecting fluctuations in transthoracic impedance that correspond with pulsatile blood flow;

[0023] FIG. 2 is a pictorial diagram of a defibrillator and electrodes constructed in accordance with the present invention and attached to a patient;

[0024] FIG. 3 is a block diagram of major components of the defibrillator shown in FIG. 2;

[0025] FIG. 4 is a flow diagram of a pulse detection process performed in accordance with the present invention;

[0026] FIG. 5 is a flow diagram of a pulse rate analysis performed in accordance with the present invention the pulse detection process shown in FIG. 4;

[0027] FIG. 6 is a flow diagram of another pulse detection process performed in accordance with the present invention in which an impedance signal pattern analysis is performed without an ECG signal analysis;

[0028] FIG. 7 is a flow diagram of a protocol implemented by a defibrillator as shown in FIG. 2 that incorporates a pulse detection process provided by the present invention;

[0029] FIG. 8 is a flow diagram of protocol implemented by the defibrillator shown in FIG. 2 that incorporates a pulse detection process provided by the present invention;

[0030] FIG. 9 is a flow diagram of still another protocol implemented by the defibrillator shown in FIG. 2 that incorporates a pulse detection process provided by the present invention;

[0031] FIG. 10 is a flow diagram of an auto-capture detection process for cardiac pacing that uses a pulse detection process of the present invention; and

[0032] FIG. 11 is a flow diagram of a patient condition advisory process for use in a manual defibrillator or monitor which incorporates a pulse detection process of the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

[0033] A device constructed in accordance with the present invention uses measurements of a patient's transthoracic impedance to determine the presence of a cardiac pulse in the

patient. As will be appreciated from the description herein, the device may be a stand alone unit or it may be incorporated into another monitoring or therapy-providing device. In one suitable application, the present invention is implemented in a defibrillator, such as the defibrillator **10** shown in FIG. 2. A patient **40** is connected to the defibrillator **10** via electrodes **12, 14** placed on the skin of the patient. The defibrillator **10** uses the electrodes **12, 14** to deliver defibrillation pulses to the patient **40**. The defibrillator **10** also uses the electrodes **12, 14** to obtain ECG signals from the patient **40**.

[0034] The electrodes **12, 14** are further configured to communicate an impedance-sensing signal through the patient **40**. The impedance-sensing signal is used by the defibrillator **10** to observe the patient's impedance. Alternatively, the defibrillator **10** may use sensors **20, 22** that are separate from the electrodes **12, 14** for communicating the impedance-sensing signal through the patient. The sensors **20, 22** may be connected to the electrodes **12, 14**, as shown in FIG. 2, they may be attached to the patient **40** via separate wires (not shown) connected to the defibrillator **10**. In either case, the sensors **20, 22** may be suitably constructed from standard external patient electrodes known in the art.

[0035] The defibrillator **10** measures the impedance of a patient between the electrodes **12, 14** (or between the sensors **20, 22**, as the case may be) when placed on the patient **40**. An impedance measuring component of the defibrillator **10** is preferably used to measure the patient's impedance.

[0036] A preferred embodiment of the invention uses a high-frequency, low-level constant current technique to measure the patient's transthoracic impedance, though other known impedance measuring techniques may be used. A signal generator included in the defibrillator **10** produces a low-amplitude, constant current, high-frequency signal (typically sinusoidal or square). The signal is preferably generated having a frequency in the range of 10 kHz-100 kHz. The current flows between the electrodes **12** and **14**. The resulting current flow causes a voltage to develop across the patient's body that is proportional to the product of the patient's impedance and the applied current. To calculate the patient's impedance, the impedance measuring component in the defibrillator **10** divides the measured sensing voltage by the applied current. Since the measured voltage is linearly related to the patient's impedance, the impedance signal data used herein may either be a calculated impedance signal or the measured voltage signal.

[0037] While embodiments of the invention specifically described herein are shown implemented in a defibrillator **10** the present invention is not limited to such specific type of application. Those of ordinary skill in the art will recognize that the advantages of the invention may similarly be achieved by implementing the present invention in cardiac monitors and other types of medical equipment that do not necessarily provide defibrillation therapy.

[0038] Prior to discussing various pulse detection processes that the defibrillator **10** may implement in accordance with the present invention, a brief description of certain major components of the defibrillator **10** is provided. Referring to FIG. 3, the defibrillator **10** includes defibrillation electrodes **30** (e.g., electrodes **12, 14** described above in FIG. 2). An impedance-sensing signal generator **56** communicates an impedance-sensing signal through the patient via the electrodes **30**. A signal amplifier **32** amplifies the impedance-

sensing signal to a level appropriate for digitization by analog-to-digital (A/D) converter **36**. A bandpass filter **34** filters the amplified impedance-sensing signal to isolate the portion of the signal that most closely reveals fluctuations due to blood flow from cardiac pulses. In one embodiment of the invention, the bandpass filter **34** is a 1-10 Hz bandpass filter. Fluctuations in the impedance signal below 1 Hz are more likely to be caused by respiration in the patient, and not blood flow. Accordingly, the bandpass filter attenuates that component of the impedance signal. The portion of the impedance signal exceeding 10 Hz is more likely affected by surrounding noise and is likewise filtered out.

[0039] The filtered impedance signal is delivered to the A/D converter **36** that converts the impedance signal into digital impedance data for further evaluation. The bandpass filter **34** or other filter may be provided to reduce any aliasing introduced in the impedance signal by the A/D converter **36**. The parameters of such filtering depend, in part, on the sampling rate of the A/D converter. Bandpass and antialiasing filters, as well as A/D converters, are well-known in the art, and may be implemented in hardware or software, or a combination of both. For example, a preferred embodiment uses a hardware lowpass filter on the impedance signal before the A/D converter **36**, and then a software highpass filter on the digital impedance data after the A/D conversion. Another preferred embodiment additionally uses a software lowpass filter after the A/D conversion to further limit the bandwidth of the impedance signal. The A/D converter **36** delivers the digital impedance signal data to the processing unit **38** for evaluation.

[0040] The processing unit **38** evaluates the impedance signal data for the presence of a cardiac pulse. The processing unit **38** is preferably comprised of a computer processor that operates in accordance with programmed instructions stored in a memory **40** that implement a pulse detection process **42**, described in more detail below. The processing unit **38** may also store in the memory **40** the impedance signal data obtained from the patient, along with other event data and ECG signal data. The memory **40** may be comprised of any type or combination of types of storage medium, including, for example, a volatile memory such as a dynamic random access memory (DRAM), a nonvolatile static memory, or storage media such as a magnetic tape or disk drive or optical storage unit (e.g., CD-RW).

[0041] The processing unit **38** may report the results of the pulse detection process to the operator of the defibrillator **10** via a display **48**. The processing unit **38** may also prompt actions (e.g., CPR) to the operator to direct the resuscitation effort. The display **48** may include, for example, lights, audible signals, alarm, printer, or display screen. The processing unit **38** may also receive input from the operator of the defibrillator **10** via an input device **46**. The input device **46** may include one or more keys, switches, buttons, or other types of user input devices.

[0042] The defibrillation electrodes **30** may further be used to sense the patient's electrocardiogram (ECG) signals. ECG signals obtained from the patient may be amplified and filtered in a conventional manner, and converted into digitized ECG data for evaluation by the processing unit **38**.

[0043] Preferably, the processing unit **38** evaluates the ECG signals in accordance with programmed instructions stored in the memory **40** that carry out an ECG evaluation

process **44** to determine whether a defibrillation shock should be provided. A suitable method for determining whether to apply a defibrillation shock is described in U.S. Pat. No. 4,610,254, which is assigned to the assignee of the present invention and incorporated by reference herein. If the processing unit **38** determines that delivery of a defibrillation pulse is appropriate, the processing unit **38** instructs a defibrillation pulse generator **50** to prepare to deliver a defibrillation pulse to the patient. In that regard, the defibrillation pulse generator **50** uses an energy source (e.g., battery) to charge one or more defibrillation capacitors in the defibrillator **10**.

[**0044**] When the defibrillation charge is ready for delivery, the processing unit **38** advises the operator via the display **48** that the defibrillator **10** is ready to deliver the defibrillation pulse. The processing unit **38** may ask the operator to initiate the delivery of the defibrillation pulse. When the operator initiates delivery of the defibrillation pulse (e.g., via the input device **46**), the processing unit **38** instructs the defibrillation pulse generator **50** to discharge through the patient the energy stored in the defibrillation capacitors (via the electrodes **30**). Alternatively, the processing unit **38** may cause the defibrillation pulse generator **50** to automatically deliver the defibrillation pulse.

[**0045**] While FIG. 3 illustrates certain major components of the defibrillator **10**, those having ordinary skill in the art will appreciate that the defibrillator **10** may contain more or fewer components than those shown. The disclosure of a preferred embodiment of the defibrillator **10** does not require that all of the general conventional components be shown. It will further be appreciated that the invention may be implemented in a cardiac monitor having essentially the same components as the defibrillator **10** shown in FIG. 3, except that the cardiac monitor does not have the components necessary for delivering a defibrillation pulse. Furthermore, some or all of the programmed instructions **42**, **44** may be implemented in hardware as an alternative to software instructions stored in the memory **40**.

[**0046**] As noted above, the present invention uses a portion of the impedance-sensing signal whose frequency range is most likely to reveal fluctuations indicating the presence of a cardiac pulse in the patient. The presence of characteristic fluctuations in patient impedance associated with a cardiac pulse is used to identify the presence of a cardiac pulse in the patient.

[**0047**] FIG. 4 illustrates a pulse detection process **60** conducted in accordance with the present invention. The pulse detection process **60** uses an analysis of impedance signal data to determine the presence of a pulse in a patient. Preferably, the impedance signal data selected for analysis is obtained during time intervals associated with QRS complexes in the patient's ECG.

[**0048**] Beginning at block **70** the pulse detection process **60** captures both ECG and impedance signal data, synchronized in time, for a predetermined time interval (e.g., 10 seconds). Preferably, at this time, persons around the patient are advised to not touch the patient during this time interval (e.g., the device could report "analyzing now . . . stand clear"). Alternatively, the ECG and impedance capturing step may continue until the first or a specified number of QRS complexes in the ECG have been identified, or in the event of asystole or a low heart rate, a predetermined maximum period of time (e.g., 10 seconds) has passed.

[**0049**] In block **72**, the pulse detection process **60** locates all of the QRS complexes in the captured ECG signal. Identification of QRS complexes can be done using methods published in the literature and well-known to those skilled in the art of ECG signal processing. For example see, Watanabe K., et al., "Computer Analysis of the Exercise ECG: a Review," *Prog Cardiovasc Dis* 22: 423-446, 1980.

[**0050**] In block **74**, for each time that a QRS complex was identified in the ECG signal, a segment of filtered impedance signal data obtained from the captured impedance data is selected. In one embodiment of the invention, the time window of each segment of impedance data is approximately 600 milliseconds in length, and commences prior to the end of the identified QRS complex. If no QRS complexes were identified in the captured ECG signal in block **72** (as would happen for example, during asystole), there will be no segments of impedance data selected in block **74**.

[**0051**] In block **76**, one or more measurements are made on a segment of impedance signal data selected in block **74** to identify or calculate a feature indicative of a cardiac pulse. The measurements may include one or more of the following:

[**0052**] (1) peak-to-peak amplitude of the impedance signal in the segment (measured in milliohms);

[**0053**] (2) peak-peak amplitude of the first derivative of the impedance signal in the segment (measured in milliohms per second);

[**0054**] (3) energy of the impedance signal in the segment (preferably calculated by squaring and summing each of the impedance data values in the segment); or

[**0055**] (4) a pattern matching statistic.

[**0056**] As to the latter measurement (i.e., pattern matching), the segment of impedance signal data is compared with one or more previously identified impedance signal patterns known to predict the presence of a pulse. The comparison produces a pattern match statistic. Generally, in this context, the greater the value of the pattern match statistic, the closer the patient's impedance signal matches a pattern impedance signal that predicts the presence of a pulse. Other candidate measurements will be apparent to those skilled in the art, and may be used instead of, or in addition to, the aforementioned measurements. A measurement resulting from the analysis in block **76** constitutes a feature of the impedance signal data indicative of the presence of a pulse.

[**0057**] In decision block **78**, the one or more features from block **76** are evaluated to determine the presence of a cardiac pulse in the patient. The embodiment shown in FIG. 4 compares the one or more features to predetermined thresholds to determine whether or not a pulse is detected. For example, an impedance peak-to-peak amplitude measurement would be consistent with the presence of a pulse if it exceeded a certain threshold (e.g., 50 milliohms). Similarly, an impedance energy measurement would be consistent with a pulse if its magnitude exceeded a predetermined threshold. Likewise, a pattern matching statistic would be consistent with a pulse if it exceeded a predetermined threshold. If the feature exceeded the specified threshold, the pulse detection process determines that a pulse was detected, as indicated at block **80**. If the feature did not exceed the specified threshold, a pulse was not detected, as indicated at block **82**. If no segments of impedance signal data were selected in block **74** (i.e., no QRS

complexes were located in block 72 in the captured ECG), the pulse detection process 60 would determine that a pulse was not detected, as indicated at block 82.

[0058] The embodiment shown in FIG. 4 uses thresholding in block 78 to determine whether a pulse was detected. However, those skilled in the art will recognize other forms of classification and determination that may suitably be used in the invention. For example, multi-dimensional classifiers may be used in decision block 78 to determine whether a pulse was detected. For example, separate analyses of the amplitude and energy in the impedance data segment, may be performed, with the resultant outcome of each analysis constituting a detection statistic that is provided to a multi-dimensional classifier. The detection statistics may be weighted and compared in the classifier to determine an overall conclusion whether a pulse is present in the patient. In other embodiments, individual calculations of instantaneous and background amplitudes and/or energies may be provided as detection features for evaluation in a multi-dimensional classifier. Pattern match statistics may also be evaluated in the multi-dimensional classifier, as may other candidate measurements of the impedance signal data. Techniques for constructing multi-dimensional classifiers are well-known in the art. For an expanded description of classifiers suitable for use with of the invention, see, e.g., R. Duda and P. Hart, *Pattern Classification and Scene Analysis*, published by John Wiley & Sons, New York, and incorporated herein by reference.

[0059] After determining whether a pulse was detected (block 80) or not detected (block 82), the pulse detection process 60 determines whether all of the segments of impedance signal data selected in block 74 have analyzed. If not, the analysis and decision process of block 76, 78, 80, and 82 is repeated for a new impedance data segment. This continues until all of the impedance data segments selected in block 74 have been analyzed.

[0060] It is recognized that the resulting determination (pulse detected or no pulse detected) may not be the same for each impedance data segment analyzed. An additional decision step is used to determine the overall outcome of the pulse detection process 60. As indicated at decision block 86, the pulse detection process 60 may evaluate the determinations for each impedance data segment and decide that a pulse is present in the patient if a pulse was detected in a simple majority of the impedance segments analyzed. Of course, other voting schemes may be used. If, in decision block 86, a majority is found, the pulse detection process concludes that a cardiac pulse is present in the patient, as indicated at block 90. Otherwise, the pulse detection process 60 concludes that the patient is pulseless, as indicated at block 88.

[0061] Requiring a pulse to be found in more than a simple majority of the impedance data segments would improve the specificity of the detection, but decrease the sensitivity for detecting a pulse. Conversely, requiring a pulse to be found for just one impedance segment or for less than a majority of the impedance segments would improve sensitivity for detecting a pulse but decrease specificity. If the pulse detection process 60 concludes that a pulse is present in the patient, the process 60 may optionally proceed to check the pulse rate of the patient, as illustrated in FIG. 5. Turning to FIG. 5, in block 92, the number of QRS complexes (located in block 72 in FIG. 4) are counted. Decision block 94 subsequently compares the number of QRS complexes to a threshold. In one

preferred embodiment, the threshold is 5, corresponding to a heart rate of approximately 30 bpm. If the number of QRS complexes is at least equal to the threshold, the pulse detection process 60 proceeds to block 96, concluding that the patient has a pulse and an adequate pulse rate. If the number of QRS complexes is less than the threshold, the pulse detection process 60 proceeds to block 98, concluding that the patient has a pulse, but also severe bradycardia.

[0062] While a preferred embodiment of the invention as shown in FIG. 4 includes capturing both ECG and impedance signal data, and selecting the segments of impedance signal data based on QRS complexes located in the ECG, other embodiments of the invention may not capture or use the ECG signal. In FIG. 6, an alternative pulse detection process 100 begins by capturing only impedance signal data from the patient, as indicated at block 102. Depending on the length of the time interval in which impedance data is captured, it may be advantageous to select a segment of the impedance signal data for further analysis, as indicated at block 104. In that regard, one suitable selection process includes scanning the impedance signal data for the maximum peak and selecting a segment of data that surrounds the detected maximum peak.

[0063] For exemplary purposes, the pulse detection process 100 is shown evaluating the selected segment of impedance signal data using a pattern match analysis. However, those skilled in the art will recognize that other techniques (e.g., analysis of the amplitude or energy in the impedance signal data, as discussed above, may be used.) In block 106, the selected impedance data segment is compared with previously identified impedance signal patterns known to predict the presence of a pulse. The resulting pattern match statistic is evaluated against a threshold in decision block 108 to determine whether a pulse was detected in the patient. If the pattern match statistic exceeded the threshold, the pulse detection process 100 concludes in block 110 that a pulse was detected in the patient. Otherwise, the pulse detection process 100 concludes that the patient is pulseless, as indicated in block 112. At this point, the pulse detection process is finished. Alternatively, if a pulse was detected in the patient, the pulse detection process 110 may proceed to evaluate the patient's pulse rate in a manner described in reference to FIG. 5.

[0064] As noted above, the transthoracic impedance signal can contain fluctuations due to cardiac pulses, respiration, or patient motion. To assess whether a patient has a pulse, it is desirable to suppress fluctuations in the patient's impedance that are due to causes other than cardiac pulses. Fluctuations due to noncardiac causes may contain components at frequencies similar to those of impedance fluctuations due to cardiac pulses. Consequently, bandpass filtering may not always adequately suppress fluctuations due to noncardiac causes.

[0065] Signal averaging of the impedance signal can be used to suppress fluctuations that are due to noncardiac causes. Signal averaging makes advantageous use of the fact that impedance fluctuations due to cardiac pulses are synchronized to QRS complexes in the ECG signal, whereas other impedance fluctuations are asynchronous to QRS complexes. Pulse detection may be more accurately accomplished using an averaged impedance signal.

[0066] A preferred method for signal averaging of the impedance signal first stores the continuous ECG and transthoracic impedance signals, synchronized in time, for a pre-

determined time interval (e.g., ten seconds). The locations of the QRS complexes (if any) in the stored ECG signal are determined. Using true mathematical correlation (or an alternative correlation technique such as area of difference), the QRS complexes are classified into types, where all QRS complexes of the same type have high correlation with the first occurring QRS complex of that type. The dominant QRS type is selected as the type containing the most members, with a preference for the narrowest QRS type when a two or more types tie for most members. Using the first QRS of the dominant type as a reference complex, the second QRS complex of the same type is shifted in time until it is best aligned with the reference complex (i.e., it achieves a maximum correlation value). The corresponding impedance signal is also shifted in time to stay synchronized with the time-shifted QRS complex. When the second QRS complex is optimally aligned with the reference complex, the two QRS complexes are averaged together. Their corresponding impedance signals, over a time period from about the start of the QRS complex to about 600 milliseconds after the end of the QRS complex, are also averaged together. The averaged QRS complex is then used as a new reference complex and the process of averaging both the QRS complexes and the corresponding impedance data is repeated with the remaining QRS complexes of the dominant type.

[0067] Preferably, during the subsequent averaging of the QRS complexes and impedance segments, the new QRS complex and impedance segment carry a weight of one and the previous averaged QRS complex and impedance segment carry a weight equal to the number of QRS complexes that have been included in the averaged QRS complex. When all of the QRS complexes of the dominant type have been processed as described above, the averaged impedance segment is evaluated using one or more of the techniques previously described (e.g., amplitude, energy, pattern matching), or by using another measuring technique known in the art, to determine whether or not the patient has a pulse.

[0068] During severe bradycardia, there will be few QRS complexes in a 10-second period and signal averaging of the transthoracic impedance signal will not be as effective as when the heart rate is higher. However, at very low heart rates, there is unlikely to be enough blood flow to support life. For that reason, below a certain heart rate (e.g., 30 bpm), the patient may be considered pulseless.

[0069] The pulse detection process of the present invention may be used as part of a shock advisory protocol in a defibrillator for determining whether to recommend defibrillation or other forms of therapy for the patient. FIG. 7 illustrates a pulse detection/defibrillation process 130, preferably for use in an automated external defibrillator (AED) capable of providing a defibrillation pulse if a patient is determined to be pulseless and in VF or VT.

[0070] In the pulse detection defibrillation process 200 in FIG. 7, the AED initializes its circuits when it is first turned on, as indicated at block 132. The defibrillation electrodes of the AED are placed on the patient. When the AED is ready for operation, the process 130 performs an analysis of the patient, as indicated at block 134, in which the AED obtains selected parameters such as impedance signal data and ECG data from the patient. During the analysis performed in block 134, the AED preferably reports "Analyzing now . . . stand clear" to the operator of the AED.

[0071] Using the information obtained in the patient analysis, the process 130 determines in decision block 136 whether the patient is experiencing ventricular fibrillation (VF). If VF is present in the patient, the process 130 proceeds to block 142 where the AED prepares to deliver a defibrillation pulse to the patient. In that regard, an energy storage device within the AED, such as a capacitor, is charged. At the same time, the AED reports "Shock advised" to the operator of the AED.

[0072] Once the energy storage device is charged, the process 130 proceeds to block 144 where the AED is ready to deliver the defibrillation pulse. The operator of the AED is advised "Stand clear . . . push to shock." When the operator of the AED initiates delivery of the defibrillation pulse, the process 130 delivers the defibrillation shock to the patient, as indicated in block 146.

[0073] The AED preferably records in memory that it delivered a defibrillation pulse to the patient. If the present pulse delivery is the first or second defibrillation shock delivered to the patient, the process 130 may return to block 134 where the patient undergoes another analysis. On the other hand, if the pulse delivery was the third defibrillation pulse to be delivered to the patient, the process 130 may proceed to block 140 where the AED advises the operator to commence providing CPR therapy to the patient, e.g., by using the message "Start CPR." The "No shock advised" prompt shown in block 140 is suppressed in this instance. The AED may continue to prompt for CPR for a predetermined time period, after which the patient may again be analyzed, as indicated in block 134.

[0074] Returning to decision block 136, if VF is not detected in the patient, the process 130 proceeds to decision block 138 and determines whether a cardiac pulse is present in the patient. The pulse detection performed in block 138 may be one of the pulse detection processes 60 or 100 described above.

[0075] If, at decision block 138, a pulse is detected in the patient, the process 130 proceeds to block 139 and reports "Pulse detected . . . start rescue breathing" to the operator. The process 130 may also report "Return of spontaneous circulation" if a pulse is detected in the patient any time after the delivery of a defibrillation pulse in block 146. In any event, after a predetermined time period for rescue breathing has completed, the process 130 preferably returns to block 134 to repeat an analysis of the patient.

[0076] If a cardiac pulse is not detected at decision block 138, the process 130 determines whether the patient is experiencing ventricular tachycardia (VT) with a heart rate of greater than a certain threshold, e.g., 100 beats per minute (bpm), as indicated at decision block 141. Other thresholds such as 120, 150, or 180 bpm, for example, may be used. If the determination at decision block 141 is negative, the process 130 proceeds to block 140 and advises the operator to provide CPR therapy. Again, at this point, the AED reports "No shock advised . . . start CPR" to the operator. The prompt to provide CPR is provided for a defined period of time. When the period of time for CPR is finished, the process 130 preferably returns to block 134 and performs another analysis of the patient. If the determination at decision block 141 is positive (i.e., the patient is experiencing VT with a heart rate greater than the threshold), the process 130 performs the shock sequence shown at blocks 142, 144, 146 to deliver a defibrillation pulse.

[0077] Variations and additions to the process 130 within the scope of the invention are recognized by those having

ordinary skill in defibrillation and cardiac therapy. FIG. 8, for example, illustrates an alternative pulse detection/defibrillation process 150 for use in an AED. As with the process 130 in FIG. 7, the AED begins by initializing its circuits at block 152. At block 154, the AED performs an analysis of the patient in a manner similar to that described with respect to block 134 in FIG. 7. After completing the analysis of the patient, the process 150 proceeds to decision block 156 to determine whether a pulse is present in the patient. The pulse detection performed in block 156 maybe, for example, any one of the pulse detection processes 60 or 100 discussed above.

[0078] If a pulse is detected in the patient, the process 150 may enter a monitoring mode at block 158 in which the patient's pulse is monitored. The pulse monitoring performed at block 158 may use any one or a combination of the pulse detection processes described herein. Preferably, the process 150 is configured to proceed from block 158 to block 154 after expiration of the predetermined monitoring time period. If the pulse monitoring at block 158 determines that at any time a pulse is no longer detected, the process 150 returns to block 154 to perform another analysis of the patient. The process 150 also preferably reports the change in patient condition to the operator.

[0079] If, at decision block 156, a pulse is not detected in the patient, the process 150 proceeds to decision block 160 where it determines whether the patient has a shockable cardiac rhythm (e.g., VF or VT). As referenced earlier, U.S. Pat. No. 4,610,254, incorporated herein by reference, describes a suitable method for differentiating shockable from non-shockable cardiac rhythms.

[0080] If a shockable cardiac rhythm, such as VF or VT, is detected, the process 150 proceeds to a shock delivery sequence at blocks 162, 164, and 166, which may operate in a manner similar to that described with respect to blocks 142, 144, and 146 in FIG. 7. If the pulse delivery was the third defibrillation shock delivered to the patient, the process 150 may proceed to block 168 and prompt the delivery of CPR, as discussed with block 140 in FIG. 7.

[0081] If VF or VT is not detected at decision block 160, the process 150 checks for asystole, as indicated at block 167. One suitable process for detecting asystole is described in U.S. Pat. No. 6,304,773, assigned to the assignee of the present invention and incorporated herein by reference. If asystole is detected at block 167, the process 150 proceeds to prompt the delivery of CPR, as indicated at block 168. If asystole is not detected, the process 150 determines that the patient is experiencing pulseless electrical activity (PEA), as indicated at block 169. PEA is generally defined by the presence of QRS complexes in a patient and the lack of a detectable pulse, combined with no detection of VT or VF. As described above, detection of PEA in block 168 is achieved by ruling out the presence of a pulse (block 156), detecting no VF or VT (block 160), and detecting no asystole (block 167). Alternatively, if the ECG signal is monitored for QRS complexes (e.g., as shown at block 70 in FIG. 4), the process 150 may conclude the patient is in a state of PEA if it repeatedly observes QRS complexes without detection of a cardiac pulse associated therewith. If a PEA condition is detected, the process 150 proceeds to block 170 and prompts the operator to deliver PEA-specific therapy to the patient. One suitable method of treating PEA is described in U.S. Pat. No. 6,298,

267, incorporated by reference herein. The process 150 may prompt other therapies as well, provided they are designed for a PEA condition. After a PEA-specific therapy has been delivered to the patient, possibly for a predetermined period of time, the process 150 returns to block 154 to repeat the analysis of the patient.

[0082] FIG. 9 illustrates yet another pulse detection/defibrillation process 200 that may be used in an AED. At block 202, after the AED has been turned on, the AED initializes its circuits. The defibrillation electrodes are also placed on the patient. The AED is then ready to analyze the patient, as indicated at block 204. This analysis may be performed in a manner similar to that described with respect to block 134 in FIG. 7.

[0083] If at any point the AED determines that the defibrillation electrodes are not connected to the AED, the process 200 jumps to block 206 where the AED instructs the operator to "Connect electrodes." When the AED senses that the electrodes are connected, the process 200 returns to the analysis in block 204. Likewise, if the AED finds itself in any other state where the electrodes are not connected, as represented by block 208, the process 200 jumps to block 206 where it instructs the operator to connect the electrodes.

[0084] Furthermore, during the analysis performed in block 204, if the AED detects motion on the part of the patient, the process 200 proceeds to block 210 where the AED reports to the operator of the AED "Motion detected . . . stop motion." If the patient is moved during the analysis process 204, the data obtained during the analysis is more likely to be affected by noise and other signal contaminants. Motion of the patient may be detected in the impedance signal data collected by the present invention. A suitable method for detecting motion of the patient is described in U.S. Pat. No. 4,610,254, referenced earlier and incorporated by reference herein. The AED evaluates the impedance measured between the defibrillation electrodes placed on the patient. As noted earlier, noise and signal components resulting from patient motion cause fluctuations in the impedance signal, generally in a frequency range of 1-3 Hz. If the measured impedance fluctuates outside of a predetermined range, the AED determines that the patient is moving or being moved and directs the process 200 to proceed to block 210. When the motion ceases, the process 200 returns to the analysis in block 204.

[0085] The process 200 next proceeds to decision block 212 where it determines whether a pulse is detected in the patient. Again, the pulse detection processes performed in decision block 212 may be, for example, one of the pulse detection processes 60 or 100 described above.

[0086] If a pulse is not detected in the patient, the process 200 proceeds to decision block 214 where it determines whether the patient has a shockable cardiac rhythm (e.g., VF or VT or a non-shockable cardiac rhythm (such as asystole and bradycardia)). As referenced earlier, one suitable method for differentiating shockable from non-shockable cardiac rhythms is disclosed in U.S. Pat. No. 4,610,254, incorporated herein by reference. If the patient's cardiac rhythm is determined to be shockable (e.g., VF or VT is found), the process 200 proceeds to blocks 216, 218, and 220 to deliver a shock to the patient. The shock delivery may be performed as described earlier with respect to block 142, 144, 146 in FIG. 7.

[0087] If the pulse delivery was the third defibrillation pulse to be delivered to the patient, the process 200 proceeds

to block **222** where the AED advises the operator to commence providing CPR therapy to the patient. The CPR prompt may continue for a defined period of time, at which the process **200** returns to block **204** and performs another analysis of the patient.

[**0088**] If, at decision block **214**, the patient's cardiac rhythm is determined not shockable, the process **200** preferably proceeds to block **222** and advises the operator to provide CPR therapy, as discussed above.

[**0089**] Returning to decision block **212**, if a pulse is detected in the patient, the process **200** proceeds to decision block **224** where it determines whether the patient is breathing. In that regard, the AED may again use the impedance signal for determining whether a patient is breathing. As noted earlier, fluctuations in impedance of the patient below 1 Hz are largely indicative of a change in volume of the patient's lungs. The breathing detection at block **224** (and at blocks **226** and **228**, discussed below) may monitor the impedance signal for characteristic changes that indicate patient breathing, e.g., as described in Hoffmans et al., "Respiratory Monitoring With a New Impedance Plethysmograph," *Anesthesia* 41: 1139-42, 1986, and incorporated by reference herein. Detection of breathing may employ a process similar to that described above for detection of a pulse (i.e., evaluating impedance amplitude, energy, or pattern), though a different bandpass filter would be used to isolate the frequency components that more closely demonstrate patient breathing. If automatic means for detecting breathing in the patient are not available, the AED may ask the operator of the AED to input information (e.g., by pressing a button) to indicate whether the patient is breathing.

[**0090**] If, at decision block **224**, the process **200** determines that the patient is not breathing, the process **200** proceeds to a block **226** where the operator of the AED is advised to commence rescue breathing. In that regard, the AED reports to the operator "Pulse detected . . . start rescue breathing." The AED also continues to monitor the patient's cardiac pulse and returns to block **204** if a cardiac pulse is no longer detected. If, at any point during the provision of rescue breathing, the AED detects that the patient is breathing on his own, the process **200** proceeds to block **228** where the AED monitors the patient for a continued presence of breathing and a cardiac pulse.

[**0091**] Returning to decision block **224**, if the process **200** determines that the patient is breathing, the process **200** proceeds to block **228** where the AED monitors the pulse and breathing of the patient. In that regard, the AED reports "Pulse and breathing detected . . . monitoring patient." If, at any time during the monitoring of the patient the process **200** determines that the patient is not breathing, the process **200** proceeds to block **226** where the operator of the AED is advised to commence rescue breathing. If a cardiac pulse is no longer detected in the patient, the process **200** proceeds from block **228** to block **204** to commence a new analysis of the patient.

[**0092**] Lastly, as noted in FIG. 9, during the rescue breathing procedure in block **226** or the monitoring procedure performed in block **228**, the AED may assess whether CPR is being administered to the patient. If the AED finds that CPR is being performed, the AED may prompt the operator to cease providing CPR. If, during the CPR period of block **222**, the AED determines that CPR is not being administered to the

patient, the AED may remind the operator to provide CPR therapy to the patient. One method for determining whether CPR is being administered is to monitor patient impedance to observe patterns of impedance fluctuation in the patient that are indicative of CPR. During CPR, repetitive chest compression typically causes repetitive fluctuations in the impedance signal.

[**0093**] FIG. 10 illustrates yet another application in which the pulse detection process of the present invention may be used. The process described in FIG. 10 pertains to auto-capture detection in cardiac pacing.

[**0094**] Specifically, the auto-capture detection process **250** begins at block **252** in which pacing therapy for the patient is initiated. A counter N, described below, is set to equal 0. At block **254**, a pacing pulse is delivered to the patient. Thereafter, filtered impedance signal data is obtained from the patient, as indicated at block **256**. The impedance data is used in block **258** to detect the presence of a cardiac pulse in the patient. The pulse detection process used in block **258** may be one of the pulse detection processes **60** or **100**, discussed above.

[**0095**] The sequence of delivering a pacing pulse and determining the presence of a cardiac pulse in blocks **254**, **256**, **258** is repeated a predetermined number of times. With respect to FIG. 10, for example, the sequence is repeated five times. At block **260**, the counter N is evaluated, and if not yet equal to 5, the counter is incremented by 1 (block **262**), following which the process **250** returns to deliver another pacing pulse to the patient.

[**0096**] If, at decision block **260**, the counter N equals 5, the process **250** determines at decision block **264** whether a cardiac pulse occurred consistently after each pacing pulse. The process **250** requires that some portion or all of the pacing pulses result in a detectable cardiac pulse before pronouncing that capture has been achieved. If the presence of a cardiac pulse is determined consistently follow the pacing pulses, the process **250** determines that capture has been achieved, as indicated at block **266**. Otherwise, the current of the pacing pulses is increased by a predetermined amount, e.g., 10 milliamperes, as indicated at block **268**. At block **270**, the counter N is set back to equal 0 and the process **250** returns to the pacing capture detection sequence beginning at block **254**. In this manner, the pacing current is increased until capture has been achieved.

[**0097**] In FIG. 10, the presence of a pulse is used to determine whether the pacing stimulus has been captured by the ventricles. Detection of QRS complexes in the patient's ECG may also be used to identify pacing capture. In that regard, the patient's ECG would be monitored along with, or in place of, the impedance data collection in block **256**. A QRS complex will occur immediately following the pacing stimulus if capture has been achieved. If QRS complexes are not observed, the current of the pacing pulses may be increased, as discussed above, until capture has been achieved.

[**0098**] FIG. 11 illustrates still another application in which the pulse detection process of the present invention may be used. The process **280** described in FIG. 11 is particularly suited for use in a manual defibrillator or patient monitor. Beginning at block **282**, the process **280** monitors the patient's ECG for QRS complexes. At block **284**, the process **280** also obtains filtered impedance signal data from the

patient. The process **280** uses the ECG and impedance signals in decision block **286** to determine the presence of a pulse. The pulse detection implemented in block **286** may be one of the pulse detection processes **60** or **100**.

[**0099**] If a pulse is detected, the process **280** determines whether a defibrillation pulse has been provided to the patient and if so, reports the return of spontaneous circulation to the operator, as indicated at block **298**. The process **280** then returns to block **282** to repeat the pulse detection analysis. If a pulse is not detected, the process **280** evaluates the ECG signal to determine whether the patient is experiencing ventricular fibrillation or ventricular tachycardia with a heart rate greater than 100 bpm. If so, then the process identifies the patient's condition and sounds a VT/VF alarm, as indicated at block **290**. If not, the process **280** then proceeds to block **292** to check for an asystole condition.

[**0100**] Detection of asystole may be accomplished as noted earlier and described in greater detail in U.S. Pat. No. 6,304,773, incorporated herein by reference. If asystole is detected, the process **280** identifies the patient's condition and sounds an asystole alarm, as indicated at block **294**. Otherwise, the patient is experiencing PEA and the patient's condition is so identified, with the sound of a PEA alarm, as indicated at block **296**. In this manner, the operator of the manual defibrillator or monitor is kept advised of the patient's condition.

[**0101**] While the preferred embodiment of the invention has been illustrated and described, it will be appreciated that various changes can be made therein without departing from the spirit and scope of the invention.

The embodiments of the invention in which an exclusive property or privilege is claimed are defined as follows:

1. A method of determining the presence of a cardiac pulse in a patient, comprising:

- (a) obtaining data derived from an impedance-sensing signal that has been communicated through the patient;
- (b) analyzing the obtained impedance signal data for a feature indicative of the presence of a cardiac pulse, wherein analyzing the impedance signal data includes evaluating energy in the impedance signal data; and
- (c) determining whether a cardiac pulse is present in the patient based on the feature in the impedance signal data.

2. The method of claim 1, wherein evaluating energy in the impedance signal data includes:

- (a) selecting data from the obtained impedance signal data for an energy calculation; and
- (b) calculating an energy in the selected impedance signal data.

3. The method of claim 2, wherein the calculated energy is the feature indicative of the presence of a cardiac pulse, the method further comprising comparing the feature to a predetermined energy threshold to determine whether a cardiac pulse is present in the patient.

4. The method of claim 1, further comprising prompting delivery of chest compressions or cardiopulmonary resuscitation to the patient if a cardiac pulse is determined not present in the patient.

5. The method of claim 1, further comprising:

- (a) obtaining electrocardiogram (ECG) data from the patient; and

- (b) determining the presence of a QRS complex in the ECG data, wherein analyzing the obtained impedance signal data for a feature indicative of the presence of a cardiac pulse further includes determining whether a QRS complex occurred in the ECG data.

6. The method of claim 5, further comprising locating a QRS complex in the ECG data and selecting impedance signal data for the energy calculation based on the located QRS complex.

7. The method of claim 1, wherein analyzing the obtained impedance signal data further includes determining cardiac output in terms of a stroke volume or rate of output, wherein the determined cardiac output is used as an additional feature indicative of the presence of a cardiac pulse, and wherein the cardiac output feature is compared to a predetermined output threshold to determine whether a cardiac pulse is present in the patient.

8. A method of determining the presence of a cardiac pulse in a patient, comprising:

- (a) obtaining data derived from an impedance-sensing signal that has been communicated through the patient;
- (b) analyzing the obtained impedance signal data for a feature indicative of the presence of a cardiac pulse, wherein analyzing the impedance signal data includes comparing the impedance signal data to a previously-identified impedance signal data pattern known to predict the presence of a cardiac pulse; and

- (c) determining whether a cardiac pulse is present in the patient based on the feature in the impedance signal data.

9. The method of claim 8, wherein the comparison produces a pattern match statistic that is the feature indicative of the presence of a cardiac pulse, the method further comprising comparing the feature to a predetermined pattern match threshold to determine whether a cardiac pulse occurred in the patient.

10. The method of claim 8, further comprising analyzing the impedance signal data for two or more features indicative of the presence of a cardiac pulse, wherein one of the features is determined from the comparison of the impedance signal data with a previously-identified impedance signal data pattern and wherein one of the other features is determined from an evaluation of an amplitude of the impedance signal data or an energy in the impedance signal data.

11. The method of claim 8, further comprising prompting delivery of chest compressions or cardiopulmonary resuscitation to the patient if a cardiac pulse is determined not present in the patient.

12. The method of claim 8, further comprising:

- (a) obtaining electrocardiogram (ECG) data from the patient; and
- (b) determining the presence of a QRS complex in the ECG data, wherein analyzing the obtained impedance signal data for a feature indicative of the presence of a cardiac pulse further includes determining whether a QRS complex occurred in the ECG data.

13. The method of claim 12, further comprising locating a QRS complex in the ECG data and selecting impedance signal data for the pattern match comparison based on the located QRS complex.

14. The method of claim 8, wherein analyzing the obtained impedance signal data further includes determining cardiac output in terms of a stroke volume or rate of output, wherein

the determined cardiac output is used as an additional feature indicative of the presence of a cardiac pulse, and wherein the cardiac output feature is compared to a predetermined output threshold to determine whether a cardiac pulse is present in the patient.

15. A medical device, comprising:

- (a) electrodes adapted for placement on a patient to sense an impedance-sensing signal that has been communicated through the patient;
- (b) a conversion circuit in communication with the electrodes for converting the sensed impedance-sensing signal into digital impedance signal data;
- (c) a processing unit in communication with the conversion circuit for processing the impedance signal data, wherein the processing unit is configured to
 - (i) analyze the impedance signal data for a feature indicative of the presence of a cardiac pulse in the patient by evaluating energy in the impedance signal data, and
 - (ii) determine whether a cardiac pulse is present in the patient based on the feature in the impedance signal data.

16. The medical device of claim 15, wherein the processing unit is configured to evaluate energy in the impedance signal data by selecting impedance signal data for an energy calculation and calculating the energy in the selected impedance signal data.

17. The medical device of claim 16, wherein the calculated energy is the feature indicative of the presence of a cardiac pulse, the processing unit being further configured to compare the feature to a predetermined energy threshold to determine whether a cardiac pulse is present in the patient.

18. The medical device of claim 15, wherein the conversion circuit and the processing unit are implemented in a defibrillator.

19. The medical device of claim 18, wherein the defibrillator is an automated external defibrillator.

20. The medical device of claim 15, wherein the processing unit is further configured to analyze the impedance signal data by determining cardiac output in terms of a stroke volume or rate of output and use the determined cardiac output as an additional feature indicative of the presence of a cardiac pulse, the processing unit being further configured to compare the additional feature to a predetermined cardiac output threshold to determine whether a cardiac pulse is present in the patient.

21. The medical device of claim 15, further comprising a display in communication with the processing unit, wherein the processing unit is further reconfigured to prompt a message on the display reporting whether a cardiac pulse is present in the patient.

22. The medical device of claim 15, further comprising a display in communication with the processing unit, wherein the processing unit is further configured to provide a graph on the display showing a representation of the impedance signal data.

23. The medical device of claim 15, further comprising electrodes adapted to sense electrocardiogram (ECG) signals in the patient, wherein the conversion circuit further converts the ECG signal received from the patient into digital ECG data, and wherein the processing unit is further configured to analyze the ECG data, determine the presence of a QRS

complex in the ECG data, and select impedance signal data corresponding in time with the QRS complex for the analysis of the impedance signal data.

24. A medical device, comprising:

- (a) electrodes adapted for placement on a patient to sense an impedance-sensing signal that has been communicated through the patient;
- (b) a conversion circuit in communication with the electrodes for converting the sensed impedance-sensing signal into digital impedance signal data; and
- (c) a processing unit in communication with the conversion circuit for processing the impedance signal data, wherein the processing unit is configured to
 - (i) analyze the impedance signal data for a feature indicative of the presence of a cardiac pulse by comparing the impedance signal data to a previously-identified impedance signal data pattern known to predict the presence of a cardiac pulse, and
 - (ii) determine whether a cardiac pulse is present in the patient based on the feature in the impedance signal data.

25. The medical device of claim 24, wherein the comparison produces a pattern match statistic that is the feature indicative of the presence of a cardiac pulse, the processing unit being further configured to compare the feature to a predetermined pattern match threshold to determine whether a cardiac pulse is present in the patient.

26. The medical device of claim 24, wherein the conversion circuit and the processing unit are implemented in a defibrillator.

27. The medical device of claim 26, wherein the defibrillator is an automated external defibrillator.

28. The medical device of claim 24, wherein the processing unit is further configured to analyze the impedance signal data by determining a cardiac output in terms of a stroke volume or rate of output and use the determined cardiac output as an additional feature indicative of the presence of a cardiac pulse, the processing unit being further configured to compare the additional feature to a predetermined cardiac output threshold to determine whether a cardiac pulse is present in the patient.

29. The medical device of claim 24, further comprising a display in communication with the processing unit, wherein the processing unit is further configured to prompt a message on the display reporting whether a cardiac pulse is present in the patient.

30. The medical device of claim 24, further comprising a display in communication with the processing unit, wherein the processing unit is further configured to provide a graph on the display showing a representation of the impedance signal data.

31. The medical device of claim 24, further comprising electrodes adapted to sense electrocardiogram (ECG) signals in the patient, wherein the conversion circuit further converts the ECG signal received from the patient into digital ECG data, and wherein the processing unit is further configured to analyze the ECG data, determine the presence of a QRS complex in the ECG data, and select impedance signal data corresponding in time with the QRS complex for the analysis of the impedance signal data.

32. The medical device of claim 24, wherein the processing unit is configured to analyze the impedance signal data for

two or more features indicative of the presence of cardiac pulse, wherein one of the features is determined from the comparison of the impedance signal data with a previously-identified impedance signal data pattern and wherein one of the other features is determined from an evaluation of an amplitude of the impedance signal data or an energy in the impedance signal data.

33. An electrotherapy device, comprising:

- (a) electrodes adapted to sense an electrocardiogram (ECG) signal from the patient;
- (b) an electrotherapy generator in communication with the electrodes for delivering electrotherapy to the patient; and
- (c) processing circuitry in communication with the electrodes and the electrotherapy generator and configured to:

analyze the patient's ECG signal for asystole, and if the patient is determined to be in an asystole condition, prompt a user for delivery of chest compressions.

34. The electrotherapy device of claim 33, wherein the electrotherapy generator and the processing circuitry are implemented in a defibrillator.

35. The electrotherapy device of claim 34, wherein the defibrillator is an automated external defibrillator.

36. The electrotherapy device of claim 33, wherein the electrotherapy generator and the processing circuitry are implemented in an automated external defibrillator and

wherein the electrodes are adapted to communicate an impedance-sensing signal through the patient and the processing circuitry is further configured to analyze the impedance-sensing signal to determine the presence of respiration in the patient, the processing circuitry prompting the delivery of rescue breathing therapy to the patient if respiration is determined not present in the patient.

37. The electrotherapy device of claim 33, wherein the electrotherapy generator and the processing circuitry are implemented in an automated external defibrillator and wherein the electrodes are adapted to communicate an impedance-sensing signal through the patient and the processing circuitry is further configured to analyze the impedance-sensing signal to determine the presence of respiration in the patient, the processing circuitry prompting the delivery of rescue breathing therapy to the patient if respiration is determined not present in the patient.

38. The electrotherapy device of claim 33 wherein the electrotherapy generator and the processing circuitry are implemented in an automated external defibrillator and wherein the electrodes are adapted to communicate an impedance-sensing signal through the patient and the processing circuitry is further configured to analyze the impedance-sensing signal to determine the presence of chest compressions being delivered to the patient, the processing circuitry prompting the delivery of chest compressions to the patient if chest compressions are not detected during a CPR period.

摘要(译)

通过评估表示患者的经胸阻抗的测量值的电信号的波动来确定患者中心脏脉搏的存在。分析从患者获得的阻抗信号数据的特征，该特征指示存在心脏脉搏。基于阻抗信号数据中的特征确定患者心脏脉搏是否存在。还可以与阻抗信号数据协调地获得心电图（ECG）数据。用于本发明的脉搏检测的各种应用包括检测PEA和促使PEA特异性治疗，促使除颤治疗和/或CPR，以及根据呼吸的检测提示救援呼吸。
