(57) **ABSTRACT**

Some embodiments of the present disclosure comprise improved systems and methods for monitoring physiological parameters such as intracranial pressure (“ICP”), intracranial temperature, and subject head position. For example, in some embodiments, an implantable apparatus for measuring ICP can be implanted into a subject skull. The apparatus can comprise an implant body having a hermetically sealed chamber housing a gas at a reference pressure, and a pressure conduction catheter having a proximal end and a distal end, wherein the distal end is configured to extend into the brain through a burr hole in the skull and includes a plurality of ports. A barrier can cover the ports of the distal end of the pressure conduction catheter, wherein the barrier and pressure conduction catheter are filled with a number of gas molecules so that the barrier is not in tension in a predefined range of ICPs.

**WIRELESS INTRACRANIAL MONITORING
SYSTEM****CROSS-REFERENCE TO RELATED
APPLICATION**

This application claims the benefit of U.S. Provisional Patent Application No. 61/981,103, entitled WIRELESS INTRACRANIAL MONITORING SYSTEM, and filed Apr. 17, 2014, the entire contents of which are incorporated herein by reference.

BACKGROUND

The present invention is directed to the field of implantable medical devices, and more specifically, medical devices for monitoring physiological parameters of a subject head.

SUMMARY

Example embodiments described herein have innovative features, no single one of which is indispensable or solely responsible for their desirable attributes. Without limiting the scope of the claims, some of the advantageous features will now be summarized.

In some cases, monitoring physiological parameters of a subject head can be desirable. For example, it can be desirable to measure the intracranial pressure (“ICP”) of a patient who has brain tumors, hydrocephalus, meningitis, Reye syndrome, and/or other conditions, or has suffered a head injury and/or head trauma. Conventional systems and methods of measuring ICP utilize a fluid column established between a patient’s ventricle and an external scale. The scale can be positioned at the same height from the floor as the tip of the catheter in the ventricles. The ICP can then be read based on the fluid levels in the fluid column. Electronic transducers can be coupled to the fluid column to provide digital readouts of the data. Variations of this technology include utilizing a catheter that contains a sealed gas bladder, and measuring the pressure read on the external end of the bladder.

These conventional methods can suffer from a number of problems. For example, the pressure measurements taken by these conventional methods can be inaccurate because they fail to take into account factors such as head temperature, barometric pressure, and patient position. The measurements can also be susceptible to noise and other measurement drift, which can include systemic errors in measurements due to changes in the measuring apparatus and/or measuring environment. The methods can also be overly invasive, restrictive, and/or uncomfortable to patients. Thus, notwithstanding the efforts of the prior art, there remains a need for providing improved systems and methods for measuring ICP and other physiological parameters.

Some embodiments of the present disclosure comprise systems and methods for monitoring physiological parameters such as ICP, intracranial temperature, and subject head position. In some embodiments, the system can comprise an implant, transceiver, and receiver interface.

In some embodiments, the implant can comprise an implant body positioned in the head of a patient. In some embodiments, a pressure conduction catheter having a fluid and/or gas column can extend from the implant body (e.g., in a distal direction). This catheter can extend from the implant body axially into a hole in a patient’s skull, into the brain. In some embodiments, the catheter can have one or

more ports (e.g., perforations, apertures, windows, holes, punctures, etc.) along its side wall. The ports can be covered by a barrier.

The implant body can comprise titanium and/or any biocompatible materials. For example, and without limitation, biocompatible materials as used herein can include stainless steel, Nickel-Titanium, Cobalt-Chromium, Pyrolytic Carbon, Nitinol, polymer materials (e.g., polyether ether ketone (“PEEK”)) and/or other suitable implant materials. The implant body can comprise a pressure-sensing diaphragm and sensors on the side of the implant body proximal to the pressure conducting catheter. The sensors can include optical sensors, strain gauges, capacitive sensors, Hall Effect sensors, and the like, and can measure stress and/or strain and/or deflection of the pressure-sensing diaphragm. In some cases, such measurements can be used to measure deformation of the diaphragm. The diaphragm can be configured to deform in response to (based on) at least in part changes in ICP. Other sensors, such as temperature sensors, oxygen sensors, pH sensors, internal pressure sensors (e.g., measuring the pressure within the implant body) and the like, can also be used. In some embodiments, the measurement of physiological parameters such as temperature can assist in determining ICP. Temperature sensors can be configured to measure the temperatures of the implant and/or implant environment. Temperature sensors can be calibrated to body temperature (e.g., 37 degrees Celsius) and/or configured to actively measure temperatures. Actively measuring temperatures may be desirable for some implants because the implant may be used in a hypothermic environment (e.g., 25 degrees to 35 degrees Celsius) and/or an environment not based on body temperature. A reference pressure can be housed within the implant body either in the main chamber of the implant body or within a separate chamber proximal to the pressure-sensing diaphragm. The reference pressure can be a gas of known pressure put into the hermetically sealed chamber. The gas can be any suitable gas. In some cases, it can be desirable for the gas to be non-reactive and/or biocompatible. In some embodiments, the gas can also be incompressible.

The implant can further comprise a wireless data antenna and wireless power receiving coil. In some embodiments, the wireless data antenna and wireless power receiving coil can be positioned on the side of the implant body distal to the pressure conducting catheter. The implant body can be hermetically sealed, wherein electronics (e.g., an electronics assembly and/or a printed circuit board assembly (“PCBA”)) for processing data within the implant body can connect to the wireless data antenna and wireless receiving coil through a hermetic feedthrough.

In some embodiments, the implant communicates with a transceiver, which can receive data (e.g., measurements) from the implant. The transceiver can process the data from the implant by applying computations, executing analytical algorithms, tagging data, and the like. The transceiver can have a user interface that enables user input and provides visual and/or output display during system operation.

In some embodiments, the implant can communicate with a receiver interface, which can interface with external systems, such as computers, electronic health record systems, mobile phones, patient monitors, and the like, for display, storage, analysis, and so forth. The implant can send data (e.g., measurements) to the receiver interface.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 illustrates a high-level flowchart of an example method of monitoring a physiological parameter of the brain.

FIG. 2 illustrates a functional block diagram of an example implant system for measuring a physiological parameter of the brain.

FIG. 3 illustrates example components of a system for measuring a physiological parameter, including an implant, transceiver, and receiving device.

FIG. 4 illustrates a perspective view of an example implant.

FIG. 5A-B illustrates a front-exploded and cross-sectional view of the example implant illustrated in FIG. 4.

FIG. 6 illustrates an exploded slanted view of the example implant illustrated in FIG. 4.

FIG. 7 illustrates a cross section view of the example implant illustrated in FIG. 4 implanted in a skull.

FIG. 8 illustrates an example implant having a single chamber housing the electronics and holding a reference pressure.

FIG. 9 illustrates an exploded slanted view of the example implant illustrated in FIG. 8.

FIG. 10A-B illustrates a front-exploded and cross-sectional view of the example implant illustrated in FIG. 8.

FIG. 11 illustrates an example implant retained in bone tissue by enclosing the device by surrounding skin tissue.

FIG. 12 illustrates an example implant retained by an example retaining gasket.

FIG. 13 illustrates an example implant having retaining protrusions.

FIG. 14 illustrates an example implant having barbs.

FIG. 15 illustrates an example implant retained by tabs that can be pulled to explant an implant.

FIG. 16 illustrates example retaining gaskets.

FIG. 17 illustrates a perspective view of an example transceiver.

FIG. 18 illustrates a perspective exploded view of the example transceiver illustrated in FIG. 17.

FIG. 19 illustrates a perspective view of an example receiver interface.

FIG. 20 illustrates a perspective exploded view of the example receiver interface illustrated in FIG. 19.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

Although certain embodiments and examples are disclosed herein, inventive subject matter extends beyond the specifically disclosed embodiments to other alternative embodiments and/or uses, and to modifications and equivalents thereof. Thus, the scope of the claims appended hereto is not limited by any of the particular embodiments described below. For example, in any method or process disclosed herein, the acts or operations of the method or process can be performed in any suitable sequence and are not necessarily limited to any particular disclosed sequence. Various operations can be described as multiple discrete operations in turn, in a manner that can be helpful in understanding certain embodiments; however, the order of description should not be construed to imply that these operations are order dependent. Additionally, the structures described herein can be embodied as integrated components or as separate components. For purposes of comparing various embodiments, certain aspects and advantages of these embodiments are described. Not necessarily all such aspects or advantages are achieved by any particular embodiment. Thus, for example, various embodiments can be carried out in a manner that achieves or optimizes one advantage or group of advantages as taught herein without

necessarily achieving other aspects or advantages as can also be taught or suggested herein.

The disclosed systems and methods for monitoring physiological parameters, such as ICP, intracranial temperature, and subject head position either independently or in conjunction, advantageously enable more accurate and/or less invasive monitoring of physiological pressures, better drift stability, increased versatility in monitoring locations, increased versatility in sizes of monitored regions, better compensation for other factors affecting sensor measurement, and better calibration of sensors. Disclosed systems and methods also provide magnetic resonance imaging ("MRI") safety (e.g., MRI compatibility) for measuring said physiological parameters. Additionally, disclosed systems and methods provide for ease of configuration and plug-and-playability for devices implantable in the brain.

Some embodiments of this disclosure can measure ICP, intracranial temperature, and/or head position (e.g., by head position monitoring). These parameters can be measured separately or in combination. These parameters can also be measured in conjunction with any one or combination of other physiological phenomena such as heart rate, respiratory rate, core body temperature, tissue oxygenation, and the like, as well as non-physiological phenomena, like barometric pressure, environmental temperature, time and the like.

FIG. 1 illustrates a high-level flowchart of an example method of monitoring a physiological parameter, which as used herein can include, without limitation, ICP, intracranial temperature, subject head position, orientation, oxygen levels, pH, and the like. In block 1, an implant can be positioned in the cranium. For example, an implant body can be implanted on the outer table of the skull but underneath the skin. A pressure conduction catheter can be coupled to the implant body and extend through a cranial burr hole into the epidural, subdural, parenchymal, or ventricular space. The burr hole can be large enough that the pressure conduction catheter can be advanced in an axial direction through the hole into the brain. The burr hole can be small enough such that the implant body may be too large to pass through the burr hole.

In block 3, data indicative of a physiological parameter from the implant can be measured. In some embodiments, the physiological parameter can be measured by a sensor that directly or indirectly measures the physiological parameter. For example, in some cases, a pressure can be directly measured by a pressure gauge. In other cases, for example, pressure can be indirectly measured by measuring changes in electrical resistance of a strain gauge measuring the strain of a diaphragm that can be configured to respond to changes in ICP. For example and without limitation, a diaphragm can be configured to deform in response to, at least in part, changes in ICP along the length of a pressure conduction catheter and/or ICP at a barrier covering at least a portion of the pressure conduction catheter.

In block 5, the data indicative of a physiological parameter can be processed. This can be performed by electronic circuitry (e.g., a controller and/or processor and/or hard-coded logic) operably coupled to the implant. In some cases, this circuitry can be disposed within the implant. In other cases, this circuitry can be located outside of the implant. Processing can include applying computations, executing analytical algorithms, tagging data, and the like. For example, and without limitation, computations can include integration, addition, multiplication, division, subtraction, rectification, upscaling, downscaling, derivation, time-scaling, correlation, convolution, and/or any mathematical operation and/or signal processing. Processing can also

5

include determining the physiological parameter from the data indicative of the physiological parameter. Such determination may use look-up tables or mathematical relationships between the measurements and the physiological parameters.

In block 7, the processed data can be transmitted to a transceiver and/or receiver interface. A person having ordinary skill in the art should appreciate that the measured data can also be directly transmitted to the transceiver and/or receiver interface, and processing (e.g., the processing described referring to block 5) can occur in the transceiver and/or receiver interface. Transceivers can have a user interface that enables user input and provides visual and/or output display during system operation. Receiver interfaces can interface with external systems, such as computers, electronic health record systems, mobile phones, patient monitors, and the like, for display, storage, analysis, and so forth of physiological data monitored by the disclosed system.

FIG. 2 illustrates a functional block diagram of an example implant system for measuring a physiological parameter. Implant 202 can be configured for positioning in a cranium. Implant 202 can comprise sensor module 222, which may comprise sensors. Some examples of sensors include, but are not limited to, optical sensors, strain gauges, capacitive sensors, Hall Effect sensors, and the like. Sensors can measure one or a combination of ICP, intracranial temperature, subject head position, orientation, oxygen levels, pH, any physiological parameter, and the like.

Sensor module 222 can be in active communication with processing unit 232 (e.g., a controller, processor, and/or central processing unit ("CPU")), which can include memory 231. Memory 231 can contain both read-only memory ("ROM") and random access memory ("RAM"), and can provide instructions and data to processing unit 231. A portion of memory 231 can include non-volatile random access memory ("NVRAM"). Processing unit 232 typically performs logical and arithmetic operations based on program instructions stored within working memory 231.

Instructions in memory 231 can be executable to implement the methods described herein. Processing unit 232 can be in active communication with power module 238 and transmitter module 236. Power module 238 can be used to power processing unit 232, transmitter module 236, sensor module 222, and/or any other component in implant 202. Transmitter module 236 can wirelessly transmit data (e.g., from processor unit 232) from implant 202 to transceiver 204 and/or receiver interface 206.

Transceiver 204 can be a device with a user interface that enables user input and provides visual and/or output display during system operation. Receiver interface 206 can be a device communicatively coupled to an external system to monitor and/or process physiological data from implant 202.

FIG. 3 illustrates example components of a system for measuring a physiological parameter, including an implant 2, transceiver 4, and receiving interface 6. Implant 2 can be either fully or partially implanted into a subject to monitor one or multiple physiological parameters. A single implant 2 can be implanted, or a plurality of implants (e.g., a plurality of implants substantially similar to implant 2). Implant 2 can be configured to wirelessly communicate with other implants, transceiver 4, and/or receiver interface 6.

Transceiver 4 can be deployed to be on-demand or in periodic, intermittent or continuous operation with implant 2, as desired for on-demand data acquisition, or to download stored data from implant 2. Transceiver 4 can be also

6

capable of wired or wireless communication with other transceivers, implants, and receiver interfaces. Transceiver 4 can be also configured to process physiological data received from implant 2, such as by applying computations, executing analytical algorithms, tagging data, and the like. Transceiver 4 can also be capable of handling data received from implant 2 for further transmissions, storage, display, or a combination thereof. Transceiver 4 can also provide visual, tactile, and auditory user interface with users to enable user input and visual and/or audio output display during system operation. Transceiver 4 can also be configured to program implant 2. For example, transceiver 4 can transmit operative instructions, software, software/firmware updates, control signals, etc.

Receiver interface 6 can be capable of wired or wireless communication with other receiver interfaces, implants, and transceivers. Receiver interface 6 can interface with external systems, such as computers, electronic health record systems, mobile phones, patient monitors, and the like, for display, storage, analysis, and so forth of physiological data monitored by the disclosed system.

In some embodiments, implant 2 can be capable of wireless communication with one or two or more or multiple transceivers (e.g., transceiver 4), one or multiple receiver interfaces (e.g., receiver interface 6), other implants (e.g., implants substantially similar to implant 2), or a combination thereof. In some embodiments, implant 2 communicates solely with a single transceiver 4 that then relays the communications in raw or processed form to other transceivers, receiver interfaces, implants or a combination thereof. In some embodiments, implant 2 communicates directly to a telemetry interface, such as Bluetooth, zigbee, Wi-Fi, or the like, of external systems, such as computers, smart phones, tablets, data capture systems, mobile telecommunications networks, or the like, without transceiver 4 or receiver interface 6 intermediaries. Wireless communication among multiple implants, transceivers, and receiver interfaces can occur sequentially, simultaneously, or both.

FIG. 4 illustrates a perspective view of an example implant. In some embodiments, implant 2 can be configured for ICP monitoring. Implant 2 can comprise implant body 8, cap 10, and pressure conduction catheter 12. As depicted in FIG. 5A-5B, which illustrate an exploded and cross-sectional view (along line A) of implant 2. Implant body 8 can house an electronics assembly 28 (e.g., a PCBA) and a power source 38 within a first internal cavity 16 that can be hermetically sealed by a cap 10 on one end and can be sealed by a hermetic feedthrough 24 on the other end. The hermetic feedthrough 24 can enable electrical connections from electronics assembly 28 to components 22 in second internal cavity 25 or outside of implant body 8 while maintaining a hermetic seal. Hermetic seals can allow for negligible fluid and gas exchange into internal cavities 16, 25, and protect internal components from damage. Second internal cavity 25 can be formed by the wall of implant body 8, hermetic feedthrough 24 and pressure sensitive diaphragm 20. Sensors 22 are disposed within the second internal cavity 25 to detect presence or magnitude of diaphragm 20 deflection caused by pressure on the external side of diaphragm 20. One or two or more of either the same type of sensors 22 or different types of sensors can be disposed within second internal cavity 25. Some examples of sensors include, but are not limited to, optical sensors, strain gauges, capacitive sensors, Hall Effect sensors, and the like. Implant 2 can have a pressure conduction catheter 12 that couples diaphragm 20 to the region targeted for pressure measurement. In some embodiments, catheter 12 may not be incorporated, and

diaphragm 20 can be positioned directly at the region targeted for pressure measurement.

In some embodiments, there can be no second internal cavity 25 in implant body 8 and/or no diaphragm 20. For example, in some embodiments, as will also later be described, implant body 8 may not have internal cavity 25, but still have diaphragm 20. In some embodiments, implant body 8 may have a second cavity 25, but no diaphragm 20. In such embodiments, other means such as, and without limitation, sensors that extend to the measuring site can be used to detect physiological parameters. Further still, some embodiments have neither second internal cavity 25 nor diaphragm 20.

In some embodiments, sensors 22 can be disposed outside of implant body 8 within the implanted environment and can be connected to the internal electronic 28 of implant 2 through hermetic feedthrough 24. In some of these embodiments, sensors 22 can be attached directly on the external face of the hermetic feedthrough 24 and can be either coupled or not coupled with a pressure conduction catheter 12. In some of these embodiments, sensors 22 can be positioned directly at the region targeted for measurement and connected via cables, wires, or leads to the external face of the hermetic feedthrough 24. In some cases, these cables, wires, or leads can extend into conduction catheter 12.

In some embodiments, physiological pressure can be measured by detecting deflection of diaphragm 20 when an external pressure is experienced against a reference pressure within second internal cavity 25. Diaphragm deflection (e.g., deflection of diaphragm 20) can be detected by different means. One such means can be measuring the time of flight for optical, electromagnetic, sonic, and/or other wave to bounce back from the diaphragm 20 to an emitter. Another means can be to measure diaphragm displacement by detecting changes in inductance or capacitance, using a linear variable displacement transformer, or Hall Effect. Diaphragm deflection can also be detected and measured by bonding an array of strain gauges 22 to diaphragm 20 in a quarter, half, or full Wheatstone bridge configuration. A person having ordinary skill the art should appreciate that any number of sensors may be used. An advantage of embodiments described in this disclosure is that the embodiments can enable off-the-shelf sensors to be used as they can be included in an implant that can have a controlled micro-environment and can measure additional physiological parameter that can affect measurements (e.g., measuring temperature as well as pressure).

In some embodiments, sensors 22 in second internal cavity 25 can measure the temperature of diaphragm 20, strain gauge 22, other components of implant 2, or a combination thereof. In some embodiments, there can be at least one temperature sensor and at least one pressure sensor. In some embodiments, there can be no temperature sensor. In some cases, pressure measurements can be susceptible to temperature-induced drift. For example, temperature changes can cause expansion and contraction of diaphragm 20, gauges 22, implant body 8, hermetic feedthrough 24, and gas within internal cavities 16, 25, which can in turn cause changes in strain experienced by the strain gauges that are not related to pressure phenomena. Other components of implant 2 can also be susceptible to physical, chemical, performance, or other changes due to temperature. Therefore, it can be advantageous to measure component temperatures to enable compensation for temperature-induced drift of physiological measurements. Temperature compensation can improve accuracy of physiological parameter

measurements. Among other advantages, component temperature can also be used as a means of diagnosing the system.

As implant 2 components can expand and contract with temperature changes. The pressure and volume of internal cavities 16, 25 can also change. In some embodiments, implant 2 can be constructed with materials that have matching or similar coefficients of thermal expansion, which can improve the predictability, stability and linearity of implant 2's structural response to temperature change. This matching can be desirable if the pressure within either or both of the internal cavities 16, 25 are used as reference pressures for pressure measurements (e.g., ICP) since structural changes affect internal pressures and volumes. As illustrated in FIG. 5B, second internal cavity 25, which serves as a reference pressure for pressure responsive diaphragm 20, can be first sealed by hermetic feedthrough 24 and secondarily sealed by cap 10. This can provide increased protection against leakage of the reference pressure. More stable, predictable, and linear reference pressures can allow for better pressure measurement accuracy.

In some embodiments, pressure responsive diaphragm 20 can be constructed from robust materials that have higher resistance to fatigue. For example, in some embodiments, diaphragm 20 can be fabricated with titanium instead of plastic; the physical properties of metal can be less susceptible to fatigue from repetitive movements associated with diaphragm deflection than those of plastics and can exhibit better drift stability. In some embodiments, pressure diaphragm 20 can be constructed from materials that are more hydrophobic, like titanium. Diaphragms made from hydrophobic material can reduce fluid impregnation and absorption of the diaphragms while implanted, thereby maintaining more consistent physical responses to pressure and more drift stability. This can generally be in contrast to diaphragms made from less hydrophobic or more hydrophilic materials—such as plastics and silicone—that can absorb or become impregnated with fluid, resulting in increased measurement drift. In some embodiments, pressure diaphragm 20 can be constructed from materials with lower permeability to reduce liquid or gas exchange across diaphragm 20 to reference pressure chamber 25 and thereby increase drift stability.

In some embodiments, diaphragm 20 can be constructed and then welded and/or otherwise attached to implant body 8. In other embodiments, diaphragm 20 can be integrated into implant body 8. In some cases, such integration can form a unibody construction between implant body 8 and diaphragm 20. For example, and without limitation, implant body 8 and diaphragm 20 can be constructed from a single piece of material (e.g., titanium). Such a unibody construction may be desirable in order to eliminate points of stress/strain and/or weakness introduced by joints. Moreover, a unibody construction may allow for a thinner and/or smaller diaphragm to be used in the implant as desired because diaphragm 20 would not be separately attached to implant body 8. For example, and without limitation, advantageously, diaphragm 20 can be constructed without extra material or thickness for attaching (e.g., welding) to implant body 8 when diaphragm 20 and implant body 8 are unibody.

Furthermore, to measure small changes in physiological pressure—such as ICP—it can be desirable for diaphragm materials to be sufficiently elastic in order to exhibit a detectable degree of deflection. Such a characteristic can be taken into account with other factors, such as adequate robustness, hydrophobicity, and permeability. In some embodiments, diaphragm 20 can be constructed from a

robust, hydrophobic, and negligibly permeable material such as titanium. In some cases, a titanium diaphragm 20 can be either very thin or large enough in surface area for a given thickness in order to exhibit sufficiently detectable deflection and sensitivity to intracranial pressures. In some cases, if diaphragm 20 is made from materials usually considered impermeable, making diaphragm 20 too thin can increase the permeability of diaphragm 20 to a level that is no longer negligible. As such, a thinner diaphragm can be desirable if it maintains adequate pressure sensitivity. However, in some cases, a thicker diaphragm 20 can exhibit increased robustness and resistance to fatigue, decreased susceptibility to noise and artifacts, and increased ease of manufacture. Therefore, in some embodiments, if a thicker diaphragm is desirable, in order to make diaphragm 20 thick enough while maintaining pressure sensitivity, the surface area of diaphragm 20 can be enlarged. In some embodiments, diaphragm 20 can comprise a titanium diaphragm made from Grade 5 titanium having a diameter of about 4 millimeters and a thickness of about 0.08 millimeters.

In some embodiments, a diaphragm 20 with a large diameter can cause the implant to be more invasive when implanted into tissue. In such cases, it can be desirable to position implant body 8 and the larger diaphragm 20 in a more superficial and less invasive location—such as outside of the skull or even the superficial of the skin—and to use a smaller pressure conduction catheter 12 to couple the diaphragm 20 to the region targeted for measurement.

The uniformity of diaphragm 20 can be related to the predictability, stability, linearity, accuracy and precision of pressure measurement. One reason for this is that models used to design as well as to calibrate diaphragms sometimes assume an ideally uniform diaphragm. Therefore, a more uniform diaphragm can perform more similarly to the models and calibrations assuming uniformity. Uniformity includes consistency in molecular structure, flatness of the diaphragm, consistency of diaphragm thickness, roughness of the diaphragm surfaces, parallelity of opposing diaphragm faces and so forth. Some methods to fabricate diaphragm 20 with high uniformity can include fabricating diaphragm 20 and the surrounding structure, such as implant body 8, out of a single piece of substrate. The assembly (e.g., including diaphragm 20 and implant body 8) can be fabricated in a single operation in a unibody fashion instead of joining separate components, which can enable greater uniformity. Furthermore, such methods can use fewer operations to fabricate the diaphragm assembly, which can lead to better conformity among fabricated diaphragm assemblies. Better conformity can enable better adherence to calibration models and intended performance.

In some embodiments, diaphragm 20 can be machined into implant body 8 by milling both sides of diaphragm 20 either sequentially or simultaneously to create a more uniform surface. In other embodiments, diaphragm 20 can first be fabricated and then affixed to the surrounding structure. In some cases, diaphragms constructed in this way can be less uniform. For example, and without limitation, a diaphragm can be first cut from a thin film of titanium, and then welded continuously along the periphery to the surrounding structure. In this example, welding can cause structural irregularity around the periphery of the diaphragm, which can make the diaphragm's response to pressure less predictable.

In some embodiments, diaphragm 20 can be fabricated with high uniformity by etching the diaphragm surfaces either after machining or in place of machining. Etching can be desirable to decrease the surface roughness of the dia-

phragms as compared to machining alone. Etching can also be desirable to produce diaphragms with more even thickness across their surfaces as compared with machining alone. For example, and without limitation, when thin diaphragms are being machined, they can deflect away from the machining tool bit more at the center than at the peripheries, resulting in a diaphragm that can be convex on one or both sides. In some cases, if such a convex shape is not desirable, methods can be performed where the diaphragms are not milled to the desired thickness. Rather, the milling operations can stop when the diaphragms are still thicker than ultimately desired and are significantly more rigid. Since the diaphragms can be thicker and more rigid at that thickness, the diaphragms can deflect significantly less away from the machining bit. This reduction in deflection can result in diaphragms that are thicker, but less convex and therefore flatter. Such thicker, flatter diaphragms can then be etched until the diaphragms reach the desired thickness. Since etching removes material uniformly across a surface, etching can result in much flatter diaphragm surfaces as compared to diaphragms that are only machined. Flatter diaphragm surfaces can ultimately lend to better predictability, stability and consistency of diaphragm responses to changes in pressure. Etching can be accomplished by dry etching or wet etching methods. Dry etching methods can comprise bombarding a substrate with ions or particles to etch out a pattern. Wet etching methods can comprise the use of chemicals to etch a pattern defined by a mask on a substrate. Wet etchants include acids and bases.

FIG. 6 illustrates an exploded slanted view of the example implant illustrated in FIG. 4. Pressure conduction catheter 12 can conduct static or dynamic pressure phenomena from distal end 52 to proximal end 44, where it couples to implant body 8 and pressure diaphragm 20. Catheter 12 can be coupled to implant body 8 using mechanical force, such as tension or compression, adhesives, locking pins, other attachment methods, or combinations thereof. The catheter 12 includes a transitional region 46 where the outer diameter of catheter 12 becomes smaller, enabling less invasive insertion through the skull and brain tissue. Dampening of the conducted pressure phenomena can be allowed, caused, or prevented by configuring the rigidity of the walls of catheter 12 through different structural designs or chemical compositions. The length of the catheter 12 from the distal surface of the body 8 to distal end 52 can be generally within the range from about 0.5 cm to about 10 cm. In some example embodiments, it can be within the range of from about 1 cm to about 8 cm. Also, in some example embodiments, it can be about 1.5 cm. The diameter of catheter 12 can be generally within the range from about 1 mm to about 5 mm. In some example embodiments, it can be within the range of from about 1 mm to about 2.5 mm. In some example embodiments, it can be about 2 mm. The thickness of the wall of catheter 12 can be generally within the range from about 0.2 mm to about 1 mm. In some example embodiments, it can be within the range of from about 0.3 mm to about 0.8 mm. Also, in some example embodiments, it can be about 0.5 mm.

In some embodiments, pressure can be conducted from a measured region of tissue through ports 53, 55 (which can be perforations, apertures, windows, holes, punctures, etc.) at distal end 52 of catheter 12 through the gas, liquid, gel or solid medium within the inner lumen of the catheter 12 up to diaphragm 20. For example, a pressure conduction catheter 12 that is 1.5 cm in length can allow measurements of the parenchymal region of the brain, and a longer catheter 12 can allow measurements of the ventricular region of the

brain. Dampening can be allowed, caused, or prevented by configuring the rigidity of said medium through different combinations of media, structural designs, chemical compositions, or combinations thereof. During the course of implantation, catheter 12, if originally filled with a medium or media either during manufacture or at the implantation site, can become partially or fully displaced with intracranial fluid. The fluid can enter due to catheter 12 insertion, capillary action along the inner surface of catheter 12, rise in intracranial pressure, or other reasons. In some cases, if catheter 12 is initially filled with a medium or media, invasion of intracranial fluid or gas can trap and possibly compress a volume of the media in proximal end 44 of catheter 12. The use of the medium or media can be desirable if direct contact between intracranial fluid or intracranial gas is not desired and the original media serves as a barrier. One example, of why direct contact between the diaphragm and intracranial fluid/gas may not be desirable is that intracranial fluid/gas can cause clotting or tissue growth on the pressure diaphragm 20 if it is in direct contact. This growth can result in pressure measurement inaccuracies or drift. If a volume of trapped original media is not desired within catheter 12 during and after implantation, a vent hole 54 can be incorporated near proximal end 44 of catheter 12. This vent hole 54 can allow the trapped original media to exit if catheter 12 is invaded by intracranial fluid or gas from distal end 52. The size and shape of vent hole 54 can be configured to allow, cause, or prevent pressure conduction dampening. Allowing catheter 12 to fill with intracranial fluid or gas can compensate for intracranial volume displacement caused by the original media in catheter 12, thereby avoiding further rises in intracranial pressure in subjects who can already have elevated pressure.

In some embodiments, configuring the length of catheter 12 can enable variability of measurement location. In some embodiments, implant 2 can be provided with a catheter 12 that is longer than desired. The user can trim the length of catheter 12 so that distal end 52 terminates at the desired measurement depth if implant 2 is inserted into the subject. In these embodiments, configuring the length of an intracranial pressure monitoring implant can enable the user to determine if pressure is monitored at the epidural, subdural, parenchymal, or ventricular depth. In some embodiments, implant 2 can be provided with multiple catheters with varying lengths, shapes, sizes and/or geometries that can be selected and attached to implant body 8 to determine monitoring modality.

In some embodiments, the effects of occlusion at distal end 52 of catheter 12 can be reduced and/or prevented with additional ports (e.g., port 53) along the side wall of catheter 12. Multiple ports can be made along the catheter to mitigate the effects of occlusion—due to, for example and without limitation, clotting, tissue growth, tissue contact, coverage, and/or other causes—of some of the ports; if some of the ports become occluded, the presence of other ports can allow continued pressure communication into catheter 12. Radial ports in catheter 12, as illustrated in FIG. 6, can mitigate the effects of occlusion at axial catheter opening 55 that can occur during catheter insertion into tissue. Multiple ports radially around catheter 12 can allow, if a directional force (e.g., gravity) is causing tissue contact to block ports on one side of catheter 12, for the ports on the opposite side to be still able to conduct pressure into catheter 12. There can also be cases where multi-directional forces, like brain edema, can cause tissue to contact and block ports in all directions. To address these cases, some embodiments of the invention can include grooves and channels on the outer surface of

catheter 12 that extend from the ports. These grooves and channels can prevent blockage and provide conduits for pressure communication into catheter 12 even if there is tissue pressing against catheter 12. In some embodiments, a barrier (e.g., barrier 813 illustrated in FIG. 8), such as a sheath, balloon, and/or covering, can be positioned along catheter 12. The barrier can be positioned such that it covers some of and/or all of the ports, and can prevent blockage of some of and/or all of the ports.

In some embodiments, different perforation patterns along catheter 12 can be used to configure the pressure monitoring region. For example, and without limitation, facing the ports in a single direction can enable directional pressure measurement. Having ports toward proximal end 44 with no distal ports can result in a shallower region of pressure measurements while ports toward distal end 52 can result in a deeper region of pressure measurement. Having tighter grouping of ports can yield a smaller region of pressure measurement, and more spread-out grouping of ports can yield a larger region of pressure measurement. Having ports along the entire length of pressure conduction catheter 12 can enable measurement across the range of depths in the brain, representing a more global intracranial pressure measurement. In contrast, some conventional intracranial pressure monitors can only measure local, regional pressures that are not representative of the pressure experienced by the organ globally. Such regional pressures can be a consequence of the compartmentalization of brain tissue. In some embodiments, if pressure conduction catheter 12 is perforated along its entire length, the pressure experienced by pressure diaphragm 20 can be the sum of pressure at all depths of the brain that the catheter traverses. This can yield a more global measurement of intracranial pressure. Again, any of the above described perforation patterns can be used in conjunction with a barrier (e.g., barrier 813 illustrated in FIG. 8), such as a sheath, balloon, and/or covering, that can be positioned such that it covers some of and/or all of the ports, and can prevent blockage of some of and/or all of the ports. In some embodiments, the barrier can be configured to not interfere with pressure measurements as will later be described. Though, even if the barrier does collapse on catheter 12 in some embodiments, pressure measurements can still be taken. Similarly, even if the barrier expands so that it is in tension (e.g., its surface is in tension), measurements can still be taken.

In some embodiments, instead of pressure sensing diaphragm 20 being integrated with implant body 8, the pressure sensor, or any other sensor, can be disposed along or at the distal end of a probe. The probe can attach to implant body 8 in a manner substantially similar to the way pressure conduction catheter 12 can be attached. Diaphragm 20 on the implant body 8 can be either perforated, or not perforated at all, and the leads for the sensors can be attached through the hermetic feedthrough 24 to the internal electronics 28. The probe can serve as mechanical support for the leads, electrical insulation, thermal insulation, liquid barrier, gas barrier, and the like or any combination thereof. The sensor or multiple sensors can be disposed in varying patterns along the probe or at the distal end of catheter 12.

These embodiments can also be configurable. Multiple probes with various lengths and different types of sensors can be provided to the user for selection and attachment to implant body 8 depending on the desired usage. The attachment of sensor leads to hermetic feedthrough 24 can be press fit or some other similar method that enables connection of sensor leads to a feed through. Some examples of sensors that could be press fitted are miniature MEMS pressure sensors,

tissue oxygenation sensors, temperature sensors, flow sensors, and the like. The use of a sensor probe can be used in conjunction with a system that incorporates an integrated pressure diaphragm with or without a pressure conduction catheter. For example, and without limitation, catheter **12** can serve as the probe and the sensor leads can be disposed directly within catheter **12**. In this example, if there is gas or fluid along the catheter alongside the sensor leads, catheter **12** can still conduct pressure to diaphragm **20**. In some embodiments, the probe that houses the sensors leads can be disposed within pressure conduction catheter **12**. In some embodiments, the probe can extend separately from implant body **8** than catheter **12**. In these embodiments, a second hermetic feedthrough (or more hermetic feedthroughs) can be incorporated into implant body **8** to enable sensor lead connection to internal electronics **28** of implant **2** in a fashion that does not interfere with the functioning of diaphragm **20**.

In some embodiments, parameters other than ICP can be measured either in substitution of or in combination with ICP. Examples of other parameters include, but are not limited to, tissue oxygenation, temperature, time, fluid flow, position, radiation exposure, and others. Sensing means for these parameters can be similarly incorporated into the body of implant **8**, attached along a probe **12**, attached to internal electronics assembly **28**, or a combination thereof.

Implant **2** can incorporate electronics assembly **28**, which can include support electronics for sensors, electronics to carry out analog-to-digital computing, and electronics to enable wireless communication. In some embodiments, electronics assembly **28** is wholly or partially disposed on one or multiple printed circuit boards (e.g., PCBAs). In some embodiments, electronics assembly **28** is comprised of analog circuitry for detecting, processing, and transmitting sensor data. In some embodiments, electronics assembly **28** can comprised digital circuitry with optional inclusion of analog support circuitry. For example, electronics assembly **28** can include one, or multiple, analog-to-digital converter modules **30**, which convert analog sensor output to a digital representation. Analog-to-digital converter modules **30** can be standalone components of the circuitry, integrated into sensor units **22**, or integrated into microcontroller processor modules **32**, which may include a controller, processor, CPU, microprocessor, application-specific integrated circuit ("ASIC"), programmable logic devices ("PLD"), field-programmable gate arrays ("FPGA"), etc. Processor modules **32** can be configured to perform one or more of: processing inputs received from sensors, filtering noise, amplifying data signals, storing data, and the like. Amplification of data signals can also occur within sensor modules **22**, as a standalone portion of the circuitry, or not occur at all. In some embodiments, components typically used to amplify sensor signals are omitted from the circuitry to conserve space in implant body **8** and enable a smaller implant **2**. In some cases, if desired, a higher bit analog-to-digital converter **30** can be used to achieve the same resolution of parameter measurement as the resolution provided by a lower bit analog-to-digital converter **30** used in conjunction with an amplifier. Another component in electronics assembly **28** can be telemetry circuitry **34**, including a wireless communication antenna **36** that enables wireless communication. In addition to enabling wireless communication, telemetry circuitry **34** can include circuitry to encode data or communications, tag transmitted data with additional information like time stamps, pre-filter, establish wireless pairing, provide communication security, etc. Telemetry circuitry **34** can be implemented as a standalone module of

electronics assembly **28** or can be incorporated wholly or in part within processing module **32**. In some embodiments, telemetry circuitry **34** implements Bluetooth low energy protocol for wireless communication with a remote device.

Electronics assembly **28** can be powered by a power source. In some embodiments, the power source can be a battery housed within implant body **8** or, alternatively, housed outside of implant body **8** and connected via a feedthrough into electronics assembly **28** within implant body **8**. In some embodiments, the power source can be a battery that is single use. In some embodiments, the power source can be a rechargeable battery that can be recharged either by conventional wired methods through a hermetic feedthrough into the implant housing or through wireless power transfer, such as inductive power transfer, optical power transfer, motion energy capture, heat capture, light capture, or the like. In some embodiments, the power source can be a fuel cell, solar cell, or means for mechanical energy storage. In some embodiments, the power source can be a capacitor that is charged wirelessly through inductive power transfer.

In some embodiments, the packaging of a wireless power-transmitting unit and a wireless power-receiving unit for transport to the deployment site can be such that the units are aligned for optimal wireless power transfer inside the package. In some embodiments where wireless power transfer is achieved through inductive coupling, the primary coil (which can send energy) can be packaged in such a way with the secondary coil (which can receive energy) that the coils can be physically aligned for maximum power transfer efficiency. The desired alignment of the primary and secondary coils used in inductive power transfer can be found by ways known by those with ordinary skill in the art. For example, and without limitation, the desired alignment can be based at least in part on maximizing the coupling factor between the power-transmitting unit and the power-receiving unit. In some embodiments, where wireless power transfer can be achieved through optical coupling, the optical source is packaged with the optical receiver in such a way that they are aligned with a clear line-of-sight for maximum power transfer efficiency. In some embodiments, when power-transmitting and power-receiving units are packaged, transported, stored and opened in such configurations at the point of deployment, the wireless power transfer functionality can be engaged, turned on, and/or started without disturbing their pre-packaged alignment. If the wireless powering is successful, the method can verify functionality of the power transfer feature. If the wireless powering is unsuccessful, the method can verify non-functionality of the power transfer feature since physical alignment can already be such that there should be maximum power transfer efficiency. In some embodiments, the system can record the wireless power transfer efficiency experienced during this ideal alignment and use that as the reference for judging wireless power performance after deployment and during operation.

In some embodiments, disclosed methods comprise packaging a power sending unit or a multitude of power sending units with a power receiving unit or a multitude of power receiving units in a packaging container in a physical configuration for a desired wireless power transfer efficiency (e.g., a maximum power transfer efficiency), opening the package and engaging the units, starting or turning on the power transfer functionality of the power sending unit(s) and the power receiving unit(s), and then verifying the power transfer.

These methods can be advantageous over other methods of checking for wireless power functionality and performance prior to deployment because the methods can test power transfer efficiency and functionality while the sending and receiving coils are in a physical configuration for maximum power efficiency. Testing wireless power functionality using other methods, such as holding the power-transmitting and power-receiving units in position manually, can be susceptible to inconsistency, imprecision, human error and other issues. This susceptibility can arise because poor wireless power functionality can result from poor physical alignment by user instead of inherent feature functionality.

In some embodiments, the power sending unit(s) and the power receiving unit(s) can be programmed during manufacture as a pair. Such programming may be desirable to allow the units to pair without pairing protocols during system deployment. In some cases, eliminating pairing protocols during system deployment may increase data security by eliminating the possibility of breach during the pairing protocols.

In some embodiments, the power source can be power-receiving coil 38. Power-receiving coil 38 is illustrated as a ring FIG. 6, but other geometries can be used for inductive power reception. In some embodiments, implant 2 can be powered transiently and can operate while in the presence of wirelessly transmitted energy. For example and without limitation, an advantage of a transient wireless power system can be the relative simplicity of the system as well as simplicity of operation. In some cases, simpler systems can have fewer failure modes and less training burden for new operators. Another advantage of transient wireless power is that the absence of stored energy reduces the safety risk of the system. For example, batteries can leak, overheat, and malfunction causing injury to the patient.

In some embodiments, implant 2 can enable passage of wireless communications and wireless power transmissions into and out of the implant internal cavity 16. In some cases, if implant cap 10 and implant body 8 are both made from conductive material, they can act as a Faraday's cage and block or attenuate electromagnetic signals into and out of internal cavity 16. Therefore, it can be desirable to incorporate a portion made from materials such as glass or ceramic that can permit passage of wireless transmissions into the implant cap 10. In some embodiments, this portion is a radiofrequency window 40 that forms a part of the implant cap 10 and allows passage of radiofrequency signals. In some cases, if wireless transmission is implemented optically, the wirelessly traversable region can serve as an optical window.

In some embodiments, the entire cap can be constructed from a wirelessly traversable material and services as a window. In some embodiments, the process for hermetically sealing implant cap 10 (e.g., made with certain materials like ceramic or glass) to implant body 8 (e.g., made from certain materials like titanium or other metals) can cause high temperatures to be applied to the entire implant assembly. Such processes include brazing and compression sealing processes. Exposing internal components (e.g., electronics assembly 28, power-receiving coil 38, and/or sensor modules 22) within implant body 8 to these high temperatures can damage or impact the performance or functionality of these internal components. Thus, in some embodiments, window 40 can be first brazed or compression sealed to rim 42 to form implant cap 10. The assembled implant cap 10 can then be hermetically sealed to implant body 8 with a process that minimizes and/or reduces global heating of

implant 2. In some embodiments, window 40 can be a ceramic disc that is brazed to a titanium ring 42 to form implant cap 10. Then, implant cap 10 can be laser welded to implant body 8. In some cases, laser welding may only generate high temperatures at the welding site and may not cause global heating of the work piece. Moreover, the work piece can be coupled to a heat-sink to ensure damaging levels of heat are not conducted from the welding site to other areas of the work piece. In these ways, some embodiments enable incorporation of hermetically sealed radiofrequency window 40 into implants 2 that contain heat-sensitive internal components.

In some embodiments, wireless power can be transmitted at 13.56 MHz, although other frequencies can be used. For example, and without limitation, implants can use any frequency within the range 100 kHz to 15 MHz depending on factors such as implant size, tissue type, and/or depth of implantation. For the implant, smaller components can be used to receive power at higher frequencies (e.g., closer to 15 MHz) than lower frequencies (e.g., closer to 100 kHz). However, higher frequency power signals can have worse tissue penetration than lower frequency power signals because higher frequency power signals can be more likely to get trapped in tissue and heat up that tissue. Accordingly, using lower frequency power signals may be desirable to power implants positioned deeper in the tissue of a patient. A person having ordinary skill in the art should appreciate that selecting a particular frequency in the aforementioned range may be done by balancing the aforementioned factors.

In some embodiments, a frequency of 13.56 MHz can be desirable because the frequency is an ISM band that can balance the tissue penetration characteristics and the size of the required supporting electronics components to yield sufficient power transfer quality while minimizing component size, and therefore invasiveness, of the implant. Another factor may be frequency density and/or interference of other operating devices. Moreover, 13.56 MHz, which is a frequency at the higher end of the 100 kHz to 15 MHz range, may be desirable because implants in the skull are close to the tissue surface and power would not need to penetrate deep into tissue. In some embodiments, wireless data can be transmitted at 2.4 GHz, although other frequencies can be used. A frequency of 2.4 GHz can be a desirable frequency because it is an ISM band. In some embodiments, the wireless power transmission frequency and the wireless communication frequency can be spread apart on the frequency spectrum to minimize interference between the two transmissions. A person having ordinary skill in the art should appreciate that there are many frequencies that can be used for transmission. For example and without limitation, data transmission can use any frequency used in the range of telecommunications, including frequencies in the range 698 MHz to 2.8 GHz. A particular frequency can be chosen based on any of the characteristics described above with respect to power signals.

In some embodiments, the data antenna and the power antenna may be integrated into a circuit that transmits and receives both data and power. For example, and without limitation, the power signal may be modulated to send data. However, in some embodiments, it may be desirable to have separate systems (e.g., components) for power and for data. Such separation may advantageously allow increased flexibility in design considerations, including the frequencies used for power and/or data transmission. In some cases, having separate systems allows for higher frequency data signals, that may allow for higher transfer rates of data than a single, integrated system. Similarly, having separate sys-

tems can also provide for higher fidelity data signals through the use of a distinct data channel. Moreover, using separate systems can allow for component modularity of the power and/or data systems, where either system can be changed, upgraded, and/or replaced. For example, and without limitation, the wireless power system may be exchanged with a battery. Also, the data system may be upgraded with advances and/or changes in communication protocols.

FIG. 7 illustrates a cross section view of the example implant illustrated in FIG. 4 implanted in a skull. Implant body **8** with integrated pressure diaphragms **20** can be implanted on the outer table of skull **102** but underneath skin **104**. Pressure conduction catheter **12** can be coupled to implant body **8** and extend through a cranial burr hole into the epidural, subdural, parenchymal, or ventricular space. In some other embodiments, implant body **8** can be secured to the outside of the scalp and catheter **12** can extend (e.g., in an axial direction) through an incision on the scalp, though a burr hole, and to the targeted measurement site. This construction can enable the use of larger, thicker pressure diaphragm designs, which can be desirable for accuracy, drift stability, and sensitivity, and can be less invasive than implanting larger diaphragms directly into the cranium.

In some embodiments, portions of implant **2** that extend into the brain (e.g., catheter **12** and/or any sensors that may extend through the catheter and/or outside of catheter **12**) may not comprise metals and/or ferrous materials. Such may be advantageous in order to make implant **2** MRI safe because metals and/or ferrous materials may have responses to MRI signals. Such response can include heating tissue and/or movement. Another advantage of not using such metals and/or ferrous materials is to provide thermal and/or electrical insulation from implant body **8** so that any heat and/or electricity generated or received on implant body **8** may not conduct to the brain tissue.

FIG. 8 illustrates an example implant having a single chamber housing the electronics and holding a reference pressure. The example implant may incorporate, or not incorporate, any of the features described in this disclosure with reference to the other figures. Encapsulation **810** can be placed on an end of implant body **808**. For example, encapsulation **810** can be placed at a surface of implant body **808** distal to a patient's skull. Encapsulation **810** can house a data antenna and power coil (e.g., data antenna **837** and/or power coil **838** illustrated in FIG. 9). In some cases, because a metal casing can act as a Faraday cage, which can cause losses in transmission efficiency and/or interference with other electronics, it may be desirable for encapsulation **810** to comprise non-conducting materials, such as (and without limitation) silicone, epoxy, glass, ceramic, and/or plastic. In this way, data antenna **837** and power coil **838** can be encapsulated and protected/insulated from the patient and other electronics of implant **802**. For example, encapsulation **810** can protect the patient tissue from coming into contact with potentially bio-incompatible materials inside. Encapsulation **810** can also protect the internal electronics from short circuiting and/or corroding due to fluid and gas ingress in the implanted setting.

For example, and without limitation, encapsulation **810** can be a preformed lid that is glued and/or epoxied onto implant body **808**. The lid can be made from a silicone mold that can be configured to fit over implant body **808**. The mold can then be filled with epoxy to cast it into the appropriate shape. In some cases, outgas from the epoxy can cause bubbles to form in the epoxy. It may be desirable to prevent such bubbles from forming. For example, and without limitation, the following methods can be used alone

or in combination to remove bubbles. In some cases, the mold and/or epoxy can be vibrated during curing. In some cases, a relative vacuum can be used to pull the bubbles out of the epoxy. In some cases, the epoxy can be cured under high pressure to prevent bubbles from forming. In some embodiments, encapsulation **810** can be a potting that is cast and formed directly on the implant. In some cases, encapsulation **810** can be cast to a lid assembly first before attaching encapsulation **810** to the rest of the implant body.

Implant body **808** can comprise titanium and/or any other biocompatible material used to enclose electronics within a hermetic seal. Implant body **808** can interface with pressure conduction catheter **812** at its proximal end through a catheter junction (e.g., catheter junction **811** illustrated in FIG. 9), which can be machined from PEEK and/or other biocompatible materials. In some cases, the catheter junction can be injection molded instead of machined.

Catheter **812** can comprise a urethane catheter. In some cases, there can be no electronics or wires inside of pressure conduction catheter **812**. Catheter **812** can provide a fluid or gas column from the target measurement area to the sensing diaphragm (e.g., diaphragm **820** illustrated in FIG. 10B). Neck **850** can interphase implant body **808** with catheter **812**.

Barrier **813**, which can be a sheath, balloon, and/or other covering, can be positioned such that it covers some of and/or all of the ports (e.g., port **853** illustrated in FIG. 9), which can include perforations, apertures, windows, holes, punctures, etc., and can prevent blockage of some of and/or all of the ports. In some embodiments, barrier **813** can be a thin-walled sac configured to protect ports from occlusion while implanted. In some embodiments, for example and without limitation, barrier **813** can be coated in a coating, gel, chemical, and/or any substance through a treatment processing such as dipping. Occlusion can result from debris clogging the ports and/or the inner lumen of catheter **812**. There can also be cellular, tissue, protein, blood clot, etc. built up to occlude the ports or catheter. An advantage of some embodiments is that even if there is growth or clotting around a portion of barrier **813**, there can still be reliable pressure conduction into and up catheter **812**. In some embodiments, barrier **813** can be laser bonded to catheter **812**. In some embodiments, barrier **813** can be adhered with glue, epoxy, a solvent bonded to form a chemical fusion, ultrasonic welding, heat welding, etc. In some embodiments, it may be desirable to make the bond between barrier **813** and catheter **812** airtight in order to prevent gas and/or liquid from entering and leaving barrier **813** and/or catheter **812**.

In some embodiments, barrier **813** may be inflated (or not inflated) so that it is not in tension. For example, and without limitation, barrier **813** can be a sac of gas and/or fluid used as a pressure conduction medium. Such can be desirable in some cases because a barrier in tension can disadvantageously act as a diaphragm and its pressure responses can change as its environment changes (e.g., changes in temperature), and/or if it uptakes fluids and/or lipids in the implanted setting. In some cases, these responses cause measurement drift. For example, a barrier in tension can disadvantageously experience gas diffusion and permeation across its membrane, which can cause the volume of gas within the barrier (and catheter) to vary based at least in part on environmental factors. In some cases, if the barrier is a balloon comprising of urethane, the balloon can disadvantageously uptake liquid and/or lipids, which can lead to drift by causing the balloon to swell. In contrast, in some embodiments, barrier **813** can comprise relatively impermeable materials to substantially prevent and/or reduce the amount

of gas, liquid, and/or lipids that can pass through barrier **813**. In some embodiments, barrier **813** can comprise polyethylene, plastic, PEEK, nylon, silicone, etc.

In some cases, a barrier not in tension may not experience some of the aforementioned responses and drift. In some embodiments, in order to create a barrier that is not in tension and does not collapse onto the catheter (e.g., blocking the ports), a number of gas molecules in a predetermined range of molecules can be used to fill the internal catheter and barrier so that the barrier is not in tension (e.g., the barrier having slack) and does not collapse onto the catheter in an operable range (e.g., a predefined operable range of measurement environment conditions, including one or more of ICP, pressure at the barrier, temperature, atmospheric pressure, position/orientation, etc.). Advantageously, by configuring the system so that the barrier neither goes in tension nor collapses on the catheter, the presence of the barrier may not introduce substantial variability (e.g., in the form of drift) to the measurements taken by the implant.

The operable range can comprise all foreseeable conditions experienced by the barrier. In this range, the number of gas molecules in the internal catheter assembly can be set so that the volume of gas sealed inside does not expand or contract with altitude changes, temperature changes, pressure changes, position changes, and/or other changes in environmental conditions to the point of putting the barrier in tension or collapsing it. For example and without limitation, typical atmospheric pressures in the measuring environment can range from 400 mmHg to 900 mmHg. ICP, while dependent on factors such as head position/orientation, atmospheric pressure, temperature, and/or other environmental factors, can typically range from -100 mmHg to 150 mmHg, where many patients will have ICPs between -20 mmHg to 50 mmHg. Accordingly, the pressure at the barrier can range from 300 mmHg to 1050 mmHg. In some cases, ICP is interpreted as cranial pressure minus atmospheric pressure. Temperature at the barrier can typically range from 15 degrees to 40 degrees Celsius. Typical operating temperature can be body temperature (e.g., around 37 degrees Celsius) or can be a hypothermic environment typically in the range of 25 degrees to 35 degrees Celsius. The volume of the catheter and the volume of the barrier (and/or a portion of the barrier that is compressible) can vary by the patient and region of the brain desired to be measured. A person having ordinary skill in the art should appreciate that the operating range can vary as desired, and systems and methods described in this disclosure can be configured to operate in those ranges. The number of gas molecules used to fill the internal catheter and barrier can be found using, at least in part, relationships between the volume, pressure, number of molecules, and temperature. For example and without limitation, the ideal gas law, $PV=nRT$ can be used, where P is the pressure, V is the volume, n is the number of molecules of gas, T is the temperature, and R is the gas constant (e.g., $0.08206 \text{ L}\cdot\text{atm}\cdot\text{mol}^{-1}\cdot\text{K}^{-1}$). In some embodiments, the desired volume of gas can be a volume greater than the static volume of the catheter in operation. This desired volume can represent the volume of gas where the barrier does not collapse onto the catheter. The desired volume of gas can also be less than the combined volume of the catheter and the static geometry of the barrier when it just comes into tension. This desired volume can represent the volume of gas where the barrier is not in tension. Assuming a predetermined range of temperatures and pressures experienced by the catheter in the implant environment, the desired number of molecules can be calculated so that the volume stays within the above-described range

where the volume is greater than the static volume of the catheter and smaller than the combined volume of the catheter and the static geometry of the barrier in the operable range. Accordingly, the number of molecules of gas can fall within a range, where any number of molecules in that range can be used. A number of molecules of gas in that range can be put into the combined catheter and barrier construction before the implant is implanted.

In some embodiments, the catheter can be filled with an incompressible fluid or gel that substantially does not expand or contract. For example, and without limitation, such incompressible fluid can comprise 0.9% saline. In some cases, 0.9% saline can prevent diffusion or osmosis by substantially matching the in-vivo ionic concentration. In some cases preventing drift with the aforementioned barrier that is not in tension can be desirable in allowing a broad spectrum of sensors, including any off-the-shelf sensor, to be compatible with embodiments of this disclosure.

In some embodiments, using a barrier may also be advantageous to take measurements over a broad area of the brain. In some patients, the patient's brain can have pockets of different pressures and/or different physiological characteristics than other portions of the brain. In conventional methods of measuring ICP and/or other physiological parameters, if sensors were placed in such a pocket, the measurements taken by the sensors may not be representative of the brain and/or region of the brain as a whole. Using a barrier can allow measurements to be taken across a broader range along the entire surface of the barrier. As discussed in this disclosure, the barrier can have different geometries and/or shapes and/or lengths as desired in order to configure the barrier to span certain segments of the brain for measurement of ICP and/or other physiological parameters.

FIG. 9 illustrates an exploded slanted view of the example implant illustrated in FIG. 8. Data antenna **837** and power coil **838** can operate as any data antenna and power coil described in this disclosure. Data antenna **837** and power coil **838** can be encased in encapsulation **810**, and implant lid **823**. A separate compartment formed by implant body **808** and implant lid **823** can house electronics and also a reference pressure. This compartment can be hermetically sealed in order to protect the patient from materials within the chamber and to protect the electronics within the chamber from the implanted setting.

Electronics assembly **828** (e.g., a PCBA) can be positioned in the compartment formed by implant body **808** and implant lid **823**. Electronics assembly **828** can comprise a processor (e.g., any processor described in this disclosure), memory (e.g., any memory disclosed in this disclosure), and/or other electronics for the functionality of the implant (e.g., any electronics described in this disclosure). Insulating layer **818** can be disposed on the proximal side of electronics assembly **828**, between electronics assembly **828** and the wall of implant body **808**. Insulating layer **818** can serve to insulate (e.g., as a non-conductor) electronics assembly **828** from implant body **808** and also hold electronics assembly **828** in place. In some cases, insulating layer **818** can be a polyimide double-sided tape.

Sensors **822** (e.g., any sensor described in this disclosure) can be positioned on the proximal side of insulating layer **818** to measure, for example and without limitation, the strain on a diaphragm (e.g., diaphragm **820** illustrated on FIG. 10B). Such measurements can be indicative of ICP and/or any other physiological parameter described in this

disclosure. Insulating layer **818** can have a hole and/or slit positioned to allow sensors **822** to electrically couple with electronics assembly **828**.

Data antenna **837** and power coil **838** can also communicate to electronics assembly **828** and/or any component within the hermetically sealed compartment formed by implant body **808** and implant lid **823** by hermetic feedthrough **824**. Hermetic feedthrough **824** can comprise pins **829**. In some cases, pins **829** can comprise tantalum, other refractory metals, and/or other biocompatible metals. In some cases, electrical connections to data antenna **837** and power coil **838** can be welded to each of data antenna **837** and power coil **838**. Any suitable material can be used for such welding. In some embodiments, tantalum pins can interface hermetic seal **828**, which can comprise glass, ceramic, and/or other insulating materials. For example, hermetic seal **828** can be CABAL **12** glass beads. In some cases, each of pins **829** can be inserted axially through holes disposed in hermetic seal **828**. These holes can pass through hermetic seal **828**, allowing pins **829** to transverse the body of hermetic seal **828**. Insulating material can pass axially through header **827**, which can comprise titanium and/or any other biocompatible material. In some cases, header **827** can comprise the same material (e.g., titanium) as implant body **808**. In some embodiments, where pins **829** comprise refractory metals (e.g., tantalum), soldering pins **829** can be difficult because refractory metals can be resistant to heat. In order to electronically connect the proximal end of these pins **829** to electronics assembly **828**, ring electrodes **826** can be laser welded to pins **829** and electronics assembly **828**. For example, and without limitation, ring electrodes **826** can comprise a platinum-iridium alloy or other solderable materials suitable for laser welding. In other embodiments, for example and without limitation, where pins **829** comprise other, non-refractory metal materials, ring electrodes **826** may not be used, and pins **829** can be soldered and/or otherwise attached directly to electronics assembly **828**.

Catheter **812** can attach to catheter junction **811** by epoxy, press-fit, screw fit, luer lock fitting, and/or any other connection. Catheter junction **811** can also be a single injection molded piece integrated with catheter **812**. Catheter junction **811** can further connect to neck **850** by epoxy, press-fit, screw fit, luer lock fitting, and/or any other connection. The inner surface of catheter junction **811** can be threaded. The threads can give greater surface area for epoxy bonding. Moreover, the threads can cast the epoxy to provide a contoured, mechanical fit, which can provide better sealing integrity between catheter junction **811** and catheter **812**. Neck **850** can further comprise flanges that allow neck **850** to contact the walls of the burr hole at consistent points. The flanges can also guide and center implant **802** into the center of the burr hole.

FIG. **10A-B** illustrates a front-exploded and cross-sectional view of the example implant illustrated in FIG. **8**. FIG. **10B** is a cross-sectional view along of FIG. **10A** along outline C. Diaphragm **820** can be positioned at the proximal end of implant body **808**, and at the distal end of catheter **812**. Diaphragm **820** can be a pressure sensing diaphragm, and/or any diaphragm as described in this disclosure. In some cases, Diaphragm **820** can be carried by and/or secured to the proximal end of catheter **812**.

A plurality of strain reliefs, such as strain relief **852**, can be positioned in the implant body **808** in order to isolate side-loading forces. In some cases, when implant **802** is placed into a burr hole in a skull, if there is a lateral force pushing on the neck region, the lateral force can deform the

pressure sensing diaphragm **820** and cause an offset in reading. For example and without limitation, such side forces can result from tissue growth and/or shifts in tissue. The strain reliefs can isolate the side-loading force from diaphragm **820**, and disperse the force elsewhere.

Standoff **851** can be at the end of implant body **808** proximal to the skull. The standoffs can facilitate the conduction of top-loading force along the walls of implant body **808**. The top-loading force can be a result of the scalp pushing down the implant into the bone. If the side of implant body **808** proximal to the skull makes contact with the rounded skull near the center neck region, that contact point can act as a pivot and there can be a lever effect that causes additional deformation of diaphragm **820**. The ridges of standoff **851** can bite into the skull bone or periosteum when the scalp holds the implant down. This can prevent the implant from sliding around and laterally within a burr hole. It can also allow external side loading forces to get loaded on the ridges instead of pushing on neck **850**. Also, in some embodiments, neck **850** may be threaded such that ridges of neck **850** thread into a burr hole.

A number of structural supporting elements can be used to retain any of the implants described in this disclosure. In some embodiments, the implant can be retained in the biological tissue by securing additional biological tissue (e.g., bone tissue) around or onto said device in a fashion that restricts movement or migration of the device within, out of, or into the biological tissue. FIG. **11** illustrates an example implant retained in biological tissue by enclosing the implant by surrounding skin tissue. Implant **701** can be retained in biological tissue **702** by enclosing implant **701** by surrounding skin tissue **703**. In some embodiments, the geometry of implant **701** can enable retention at the implantation site through unidirectional force as exerted by skin tissue **703**. In other embodiments, the geometry of implant **701** can enable retention at the implantation site through multidirectional force exerted by a single or plurality of nearby tissue bodies.

In some embodiments, an implant can be retained in the biological tissue by compressive or expansionary force that is coplanar to the implantation hole in the biological tissue. For example and without limitation, the implant can be retained using a radially outward directed structure and/or force. FIG. **12** illustrates an example implant retained by an example retaining gasket. A coplanar compressive force can be generated by retaining gaskets **304** when implant **301** is positioned in biological tissue **302**. This force can hold implant **301** in place. In some embodiments, retaining gaskets **304** can be integral features of implant **304**. In some embodiments, retaining gaskets **304** can be separate components that can be assembled with implant **301** prior to implantation into biological tissue **302**. In some embodiments, retaining gaskets **304** can be formed from elastic or compressive materials such as, but not limited to, metal, rubber, silicone, plastic and the like. In some embodiments, retaining gaskets **304** can be shaped to have continuous contact with retained implant **301**. In some embodiments, retaining gaskets **304** can be shaped not to have continuous contact with the retained implant **301**. In some embodiments, retaining gaskets **304** can be shaped to have continuous contact with the perimeter of the hole in biological tissue **302** in which implant **301** is implanted.

FIG. **13** illustrates an example implant having retaining protrusions. For example and without limitation, protrusions can include a plurality of axially elongated ridges. In some embodiments, axially elongated ridges may be helical (e.g., the ridges of a screw) to retain the implant. For example and

without limitation, retaining protrusions **406** of implant **400** can provide points of contact with the perimeter of the hole in the biological tissue in which implant **400** is implanted. In some embodiments, retaining protrusions **406** are fashioned as a single or array of spring-loaded levers or other such means of generating static compressive or expansionary force, such as, but not limited to metals, rubber, silicone, plastic and the like.

In some embodiments, an implant (e.g., any implant described in this disclosure) can be first inserted into a retaining mechanism to form an assembly, and then said assembly can be inserted into the biological tissue in which the implant is to be implanted. The implant can comprise one or more retaining mechanisms, such as sleeves, collars, and/or any other mechanisms described in this disclosure. In some embodiments, the retaining mechanism can include one or more tissue (e.g., bone and/or other biological tissues) engaging structures on the surface of a retaining structure. These tissue engaging structures can be radially directed outward from the retaining structure to the bone in order to engage the bone. The retaining structure may also have radially inward directed engagement structures in the inner surface in order to engage the implant. In some embodiments, the retaining mechanism can be first inserted into the biological tissue in which the implant is to be implanted, and then the implant can be inserted into the retaining mechanism that already resides in the biological tissue. In some embodiments, the insertion of the implant into the retaining mechanism that already resides in the biological tissue actuates, causes, or affects the compressive, expansionary, or deforming force that holds the implant in place within the implanted tissue. In some embodiments, the implant can be pushed axially into the retaining mechanism, wherein the radially inward directed structures of the retaining mechanism can engage the implant to form an assembly comprising the implant and retaining mechanism. Said assembly can then be implanted into the biological tissue.

In some embodiments, the implant can be retained permanently in the biological tissue by a retaining component such as, but not limited to, a screw or array of screws, non-elastic deformations, phase-changes, adhesion, unidirectional gates, locking mechanisms and the like that allows insertion of the device into the biological tissue in which it is implanted but resists removal. FIG. **14** illustrates an example implant having barbs to contact the surface of the biological tissue in which the implant is implanted. Implant **401** can incorporate barbs **407** (e.g., extending from surface **408**) to contact biological tissue **402** in which implant **401** is implanted.

In some embodiments, the implant can be removable from the biological tissue after the desired period of fixed implantation by incorporation of features that enable or facilitate explantation such as, but not limited to, pull tabs, loops, ejection mechanisms and the like. In some embodiments, the features that enable and/or facilitate explantation are integral to the implant. In some embodiments, the features that enable or facilitate explantation are separate components, a multitude of separate components, or a combination of integral and separate components that are assembled with the implant prior to implantation.

FIG. **15** illustrates an example implant retained by tabs that can be pulled and/or twisted to explant an implant. Implant **501** includes tabs **509** that can be pulled to explant implant **501** from biological tissue **502** in which it is implanted. In some embodiments, the features that enable and/or facilitate explantation can be folded, stowed, tucked and/or otherwise stored to create a more suitable form factor

for implantation and deployed for use at the time of explantation. In some embodiments, the tabs can work in conjunction with other retaining mechanisms described in this disclosure. For example, and without limitation, implant **501** can be retained in biological tissue **502** by a compressive force. Tabs **509** can be pulled in an axial direction. Tabs **509** can also be twist in a tangential direction so that implant **501** rotates while tabs **509** are pulled to facilitate explantation of implant **501**. As another non-limiting example, the exterior surface of implant **501** may comprise threads so that the rotation of implant **501** can unscrew it (or screw it) from biological tissue **502**.

FIG. **16** illustrates example retaining gaskets. In some embodiments, retaining gaskets can have an inner geometry suited for insertion of the implant and an outer geometry suited for insertion into the biological tissue in which the retaining gaskets are implanted. In some embodiments, the inner geometry can be configured for insertion of an implant and/or another retaining gasket (e.g., another retaining gasket in which an implant can be inserted). In some embodiments, retaining gaskets can have an outer geometry suited for insertion into other retaining gaskets. In some embodiments, retaining gaskets can have an outer geometry suited for insertion into the biological tissue in which the retaining gaskets are implanted. A plurality of retaining gaskets can enable a user to retain an implant, as in any implant described in this disclosure, in a variety of geometries of holes in biological tissues by selecting a single retaining gasket or by configuring multiple retaining gaskets to suit the geometry of the holes. Retaining gaskets can vary in geometries, including shapes such as octagons, circles, and squares as desired. Similarly, the retaining gaskets can also vary in dimensions, including thickness, length, height, size, and/or any other geometric dimension as desired.

For example, and without limitation, retaining gasket **605** can have an upper edge and a lower edge, and sidewalls therebetween. Retaining gasket **605** can have a central lumen traversing the upper edge and lower edge. The outer surface of the side walls may comprise tissue engaging structures for engaging the surface of tissues (e.g., bone and/or other biological tissue) proximal to the side walls. The tissue engaging structures may be any of the tissue engaging structures described in this disclosure. The interior surface of the central lumen may be configured to engage an implant (e.g., any implant described in this disclosure). In some embodiments, the inner surface may be threaded and/or have structures directed radially inward to engage the implant. The inner surface may also comprise any implant-engaging structure described in this disclosure. For example, and without limitation, a retaining gasket can be an octagon as illustrated in retaining gasket **605**, circular as illustrated in retaining gasket **606**, a square as illustrated in retaining gasket **607**, and/or any other geometry as desired. The dimensions of the retaining gasket can also vary as illustrated by retaining gasket **608**, which is a circular retaining gasket that is longer, wider, and thicker than circular retaining gasket **606**.

FIG. **17** illustrates a perspective view of an example transceiver. In some embodiments, transceiver **4** includes antenna **56**, which can be connected by cable **58** to transceiver body **54**. In some embodiments, antenna **56** can be fixed to cable **58** permanently. In some embodiments, antenna **56** can be plugged into and unplugged from cable **58**. In some embodiments, cable **58** can be fixed to transceiver body **54** permanently. In some embodiments, cable **58** can be plugged into and unplugged from the transceiver body **54**.

In some embodiments, transceiver 4 can be communicatively coupled with an implant (e.g., implant 2 and/or any implant described in this disclosure) to transmit power and/or data. Having a protocol for communicative coupling transceiver 4 and an implant may be advantageous in order to pair transceiver 4 with a particular implant. Such may be desirable for safety, such as in order to prevent errant modifications to implants (e.g., modifications to other implants such as pacemakers and/or other implants in the patient and/or implants in other patients). Also, such a protocol may be desirable for security, such as preventing unauthorized access to implant programming and/or powering. In some embodiments, transceiver 4 can also maintain an updatable list of implant identification ("ID") parameters in memory including, without limitation, identification numbers, model numbers, power usage characteristics, power frequencies, data frequencies, data usage characteristics and protocols, processor numbers, and/or other unique identifiers and/or combination of unique identifiers. An implant can send its identifier to the implant (e.g., via any of the means that are described below) and transceiver 4 can check if the implant is in its updatable list of implant ID parameters. If the implant is on the updatable list, transceiver 4 and the implant can communicatively couple. Other ways of pairing an implant and transceiver 4 can also be used in combination or in the alternative. For example and without limitation, password and key systems known in the art can be used to authenticate a pairing between an implant and transceiver 4 (e.g., a public/private key pairing system).

In some embodiments, the protocol for communicative coupling can use the data and/or power signals used by the implant and/or transceiver 4 to transmit/receive data and/or power. For example, and without limitation, transceiver 4 can be paired with an implant using data information sent over data communication protocols. For example and without limitation, information can be sent via the data antenna (e.g., data antenna 837) by using password and key systems known in the art (e.g., public/private key pairing). In some embodiments, an implant can send a signal with a particular frequency and/or modulation from the implant's power antenna in order to operably couple data and/or power transmission to transceiver 4. In some embodiments, transceiver 4 can send a power signal to an implant. The implant can then adjust its power consumption, which can be detected by transceiver 4 via a reverse link, where, for example, transceiver 4 detects changes in the load placed on its power circuitry due to the implant's power consumption. Based on the pattern of the changes in load (e.g., changes in the load's frequency, amplitude, etc.), transceiver 4 can determine (e.g., by checking if the pattern corresponds to an implant on its updatable list of implants) whether to communicatively couple with the implant for data and power transmission/reception.

In some embodiments, communicative pairing can be achieved using an out-of-band system (e.g., an out-of-band authentication system), where identification is transmitted/received using a different frequency, protocol, channel, and/or hardware than data and/or power. For example, and without limitation, transceiver 4 can pair with an implant using near field communication ("NFC"), such as, without limitation, radio frequency identification ("RFID"). Using NFC may be advantageous because NFC can have a confined range, which can limit communication between implant and transceivers to those that are in close proximity to each other. For example and without limitation, in some embodiments, NFC can initiate a connection only where the implant and transceiver are less than 10 cm apart. A person

having ordinary skill in the art should appreciate that the range can be adjusted based on known design choices. In some embodiments, a user interface can be used at transceiver 4 in order to select an implant to communicatively pair for transmitting and/or receiving data and/or power.

FIG. 18 illustrates a perspective exploded view of the example transceiver illustrated in FIG. 17. In some embodiments, antenna 56 can include enclosure 78, which can house power-transmitting coil 80, which sends power to an implant (e.g., implant 2 of FIG. 3), including an electronics assembly of the implant. In some embodiments, power transmitting antennae geometries other than a coil can be implemented to transmit power. In some embodiments, electronics assembly 82 includes a temperature sensing system that can be used to diagnose operational temperature of the transmitting antenna and alert the system of temperatures that can injure the subject, damage the system, or impact performance. In some embodiments, electronics assembly 82 can include a barometric pressure sensing system that can be used to measure barometric conditions to compensate pressure measured by an implant (e.g., implant 2 of FIG. 3) for barometric affects. In some embodiments, electronics assembly 82 can include a position sensor to establish antenna motion, position, orientation, and the like. Antenna position can be used to infer implant position as well as patient position, which are data that can be used to interpret physiological measurements affected by position. Certain physiological parameters, such as intracranial pressure, are significantly impacted by subject position. For example, a subject in an upright position has a lower ICP than the same subject in the same physiological state in a supine position. As such, when interpreting pressure measurements for intracranial pressure, it can be desirable to consider changes in ICP due to subject position, which can enable determinations of whether changes in measured ICP are due to factors other than position, such as due to ailment, injury, condition, and so forth. In some embodiments, data antenna 86 can be included in the electronics assembly 82. In some cases, placing data antenna 86 inside transceiver antenna 56 can significantly shortens the telemetry range to an implant in contrast to placing data antenna 86 within transceiver body 54. Decreasing the range of telemetry can increase the quality of service. It can also lower power demand for data transmission.

In some embodiments, transceiver body 54 can incorporate display screen 60 for display output to the user, user input buttons 62, electronics assembly 68, and power source 66 housed within enclosure 64. Enclosure 64 can protect transceiver body 54 from operational hazards, such as (and without limitation) drops, splashes of liquid, and impacts. Enclosure 64 can also enable attachment of transceiver body 54 to the subject, a patient bed, or other fixtures as desired. In some embodiments, display screen 60 can output measured parameters, system operational state, system identification, subject identification, other information, or a combination thereof. Examples of display screens 60 include, but are not limited to, liquid crystal displays, e-ink displays, segmented displays, and the like. In some embodiments, as depicted in FIG. 18, user input buttons 62 can be implemented to allow user operation of the system. In other embodiments, user input buttons can be substituted with touch screens, scroll wheels, track pads, keyboards, and other alternatives. In some embodiments, the electronics assembly 68 includes one, or multiple, printed circuit boards that incorporate processor modules 74, analog-to-digital converter modules 72, telemetry modules 70, and various sensors 76. In some embodiments, processor modules 74 are

capable of data storage. In some embodiments, sensors 76 are barometric sensors, temperature sensors, position sensors, motion sensors, and the like. Transceiver electronics assembly 68 can be powered by a power source 66. In some embodiments, power source 66 can be a disposable or rechargeable battery. In some embodiments, power source 66 can be mains electricity. Alternative power sources 66 can include, without limitation, solar cells, fuel cells, and the like.

FIG. 19 illustrates a perspective view of an example receiver interface. FIG. 20 illustrates a perspective exploded view of the example receiver interface illustrated in FIG. 19. In some embodiments, receiver interface 6 (FIG. 2) can comprise a portable enclosure 88 with port 100 for connection to an external system. Receiver interface 6 can incorporate electronics assembly 90, a power source 98, and an interface port 100. In some embodiments, electronics assembly 90 can include one, or multiple, printed circuit boards that incorporate processor modules 92, digital-to-analog converter modules 94, and telemetry modules 96. In some embodiments, receiver interface 6 can also incorporate sensors. In some embodiments, receiver interface 6 can incorporate user input and display means. In some embodiments, receiver interface 6 can connect with external systems by plugging directly in a port on the external system. In some embodiments, receiver interface 6 can connect to external systems through a cable. In some embodiments, receiver interface 6 can connect to external system through wireless communication means. In some embodiments, electronics assembly 98 of receiver interface 6 can be powered by power source 98. In some embodiments, power source 98 can be a disposable or rechargeable battery. In some embodiments, power source 98 can be mains electricity. In some embodiments, power source 98 may not be incorporated into receiver interface 6, which can draw power from the external system. Alternative power sources 98 can include, for example and without limitation, solar cells, fuel cells, and the like.

In some embodiments, physiological measurements can be compensated for environmental, situational, positional, or other physiological factors that impact the measurement. The disclosed system can enable inclusion of sensing, measurement, or input of these factors at each of the system components, which can include implant 2, transceiver 4, and receiver interface 6 (FIG. 2). Processing for compensation can be implemented by implant 2, transceiver 4, receiver interface 6, and/or a combination thereof. Processing can be implemented with analog circuitry, digital circuitry, or a combination of both.

A person/one having ordinary skill in the art would understand that information and signals can be represented using any of a variety of different technologies and techniques. For example, data, instructions, commands, information, signals, bits, symbols, and chips that can be referenced throughout the above description can be represented by voltages, currents, electromagnetic waves, magnetic fields or particles, optical fields or particles, or any combination thereof. A person/one having ordinary skill in the art would further appreciate that any of the various illustrative logical blocks, modules, processors, means, circuits, and algorithm steps or blocks described in connection with the aspects disclosed herein can be implemented as electronic hardware (e.g., a digital implementation, an analog implementation, or a combination of the two, which can be designed using source coding or some other technique), various forms of program or design code incorporating instructions (which can be referred to herein, for convenience,

as “software” or a “software module”), or combinations of both. To clearly illustrate this interchangeability of hardware and software, various illustrative components, blocks, modules, circuits, and steps or blocks have been described above generally in terms of their functionality. Whether such functionality is implemented as hardware or software depends upon the particular application and design constraints imposed on the overall system. Skilled artisans can implement the described functionality in varying ways for each particular application, but such implementation decisions should not be interpreted as causing a departure from the scope of the present disclosure.

The various illustrative logical blocks, modules, and circuits described in connection with the aspects disclosed herein and in connection with the figures can be implemented within or performed by an integrated circuit (“IC”), an access terminal, or an access point. The IC can include a general purpose processor, a digital signal processor (“DSP”), an ASIC, a FPGA or other programmable logic device, discrete gate or transistor logic, discrete hardware components, electrical components, optical components, mechanical components, or any combination thereof designed to perform the functions described herein, and can execute codes or instructions that reside within the IC, outside of the IC, or both. The logical blocks, modules, and circuits can include antennas and/or transceivers to communicate with various components within the network or within the device. A general purpose processor can be a microprocessor, but in the alternative, the processor can be any conventional processor, controller, microcontroller, or state machine. A processor can also be implemented as a combination of computing devices, e.g., a combination of a DSP and a microprocessor, a plurality of microprocessors, one or more microprocessors in conjunction with a DSP core, or any other such configuration. The functionality of the modules can be implemented in some other manner as taught herein. The functionality described herein (e.g., with regard to one or more of the accompanying figures) can correspond in some aspects to similarly designated “means for” functionality in the appended claims.

If implemented in software, the functions can be stored on or transmitted over as one or more instructions or code on a computer-readable medium. The steps or blocks of a method or algorithm disclosed herein can be implemented in a processor-executable software module which can reside on a computer-readable medium. Computer-readable media includes both computer storage media and communication media including any medium that can be enabled to transfer a computer program from one place to another. A storage media can be any available media that can be accessed by a computer. By way of example, and not limitation, such computer-readable media can include RAM, ROM, EEPROM, CD-ROM or other optical disk storage, magnetic disk storage or other magnetic storage devices, or any other medium that can be used to store desired program code in the form of instructions or data structures and that can be accessed by a computer. Also, any connection can be properly termed a computer-readable medium. Disk and disc, as used herein, includes compact disc (CD), laser disc, optical disc, digital versatile disc (DVD), floppy disk, and Blu-ray disc where disks usually reproduce data magnetically, while discs reproduce data optically with lasers. Combinations of the above should also be included within the scope of computer-readable media. Additionally, the operations of a method or algorithm can reside as one or any combination or set of codes and instructions on a machine readable

medium and computer-readable medium, which can be incorporated into a computer program product.

It is understood that any specific order or hierarchy of steps or blocks in any disclosed process is an example of a sample approach. Based upon design preferences, it is understood that the specific order or hierarchy of steps or blocks in the processes can be rearranged while remaining within the scope of the present disclosure. The accompanying method claims present elements of the various steps or blocks in a sample order, and are not meant to be limited to the specific order or hierarchy presented.

Various modifications to the implementations described in this disclosure can be readily apparent to those skilled in the art, and the generic principles defined herein can be applied to other implementations without departing from the spirit or scope of this disclosure. Thus, the disclosure is not intended to be limited to the implementations shown herein, but is to be accorded the widest scope consistent with the claims, the principles and the novel features disclosed herein. The word "example" is used exclusively herein to mean "serving as an example, instance, or illustration." Any implementation described herein as "example" is not necessarily to be construed as preferred or advantageous over other implementations.

Certain features that are described in this specification in the context of separate implementations also can be implemented in combination in a single implementation. Conversely, various features that are described in the context of a single implementation also can be implemented in multiple implementations separately or in any suitable sub-combination. Moreover, although features can be described above as acting in certain combinations and even initially claimed as such, one or more features from a claimed combination can in some cases be excised from the combination, and the claimed combination can be directed to a sub-combination or variation of a sub-combination.

Similarly, while operations are depicted in the drawings in a particular order, this should not be understood as requiring that such operations be performed in the particular order shown or in sequential order, or that all illustrated operations be performed, to achieve desirable results. In certain circumstances, multitasking and parallel processing can be advantageous. Moreover, the separation of various system components in the implementations described above should not be understood as requiring such separation in all implementations, and it should be understood that the described program components and systems can generally be integrated together in a single software product or packaged into multiple software products. Additionally, other implementations are within the scope of the following claims. In some cases, the actions recited in the claims can be performed in a different order and still achieve desirable results.

What is claimed is:

1. An implantable apparatus for measuring intracranial pressure (ICP) in a brain housed within a skull, comprising: an implant body having a first sealed cavity and a second cavity, the second cavity open only to a pressure conduction catheter; the pressure conduction catheter having a proximal end and a distal end, wherein the distal end is configured to extend into the brain through a burr hole in the skull and includes a plurality of ports, and the proximal end is configured to couple with the implant body; a diaphragm coupled with the implant body and configured to deform in response to changes in ICP at the plurality of ports;

- at least one sensor configured to obtain data indicative of deformation of the diaphragm; and a processor, configured to receive said obtained data and determine the ICP at the plurality of ports based at least in part on the obtained data.
2. The apparatus of claim 1, wherein the processor is positioned within the implant body.
3. The apparatus of claim 1, wherein the diaphragm and implant body are unibody.
4. The apparatus of claim 2, wherein the first sealed cavity of the implant body includes a reference pressure.
5. The apparatus of claim 2, further comprising a data antenna operably coupled to the processor.
6. The apparatus of claim 5, wherein the data antenna is coupled to the processor through a hermetic feedthrough.
7. An implantable apparatus for measuring intracranial pressure (ICP) in a brain housed within a skull, comprising: an implant body comprising a hermetically sealed chamber and a cavity, the hermetically sealed chamber housing a gas at a reference pressure and the cavity open only to a pressure conduction catheter; the pressure conduction catheter having a proximal end and a distal end, wherein the distal end is configured to extend into the brain through a burr hole in the skull and includes a plurality of ports, and the proximal end is configured to couple with the implant body; a diaphragm positioned proximal to the proximal end of the pressure conduction catheter, the diaphragm configured to deform in response to changes in ICP at the plurality of ports; and at least one sensor communicatively coupled to the processor and configured to obtain data indicative of the deformation of the diaphragm.
8. The apparatus of claim 7, wherein the diaphragm and implant body are unibody.
9. The apparatus of claim 1, further comprising a barrier configured to cover the ports of the distal end of the pressure conduction catheter, wherein the barrier and pressure conduction catheter are filled with a predetermined number of gas molecules so that the barrier is not in tension in at least a predefined range of ICPs.
10. The apparatus of claim 9, wherein the barrier is not in tension in at least a predefined range of atmospheric pressures.
11. The apparatus of claim 9, wherein the barrier does not collapse onto the pressure conduction catheter in at least the predefined range of ICPs.
12. The apparatus of claim 7, further comprising a barrier configured to cover the ports of the distal end of the pressure conduction catheter, wherein the barrier and pressure conduction catheter are filled with a predetermined number of gas molecules so that the barrier is not in tension in a predefined range of ICPs.
13. The apparatus of claim 12, wherein the barrier does not collapse onto the pressure conduction catheter in at least the predefined range of ICPs.
14. The apparatus of claim 12, wherein the barrier is not in tension in at least a predefined range of atmospheric pressures.
15. The apparatus of claim 9, wherein the predefined range of ICPs is -100 mmHg to 150 mmHg.
16. The apparatus of claim 12, wherein the predefined range of ICPs is -100 mmHg to 150 mmHg.
17. The apparatus of claim 1, where the first internal cavity is hermetically-sealed.

31

18. The apparatus of claim 1, where the diaphragm is positioned between the first sealed cavity and the second cavity.

19. The apparatus of claim 7, where the diaphragm is positioned between the hermetically sealed chamber and the 5 cavity.

摘要(译)

本公开的一些实施方案包括用于监测生理参数（例如颅内压（“ICP”），颅内温度和受试者头部位置）的改进的系统和方法。例如，在一些实施例中，可以将用于测量ICP的可植入设备植入到受试者头骨中。该装置可包括植入物本体和压力传导导管，所述植入物本体具有容纳基准压力下的气体的气密密封腔室，所述压力传导导管具有近端和远端，其中所述远端构造造成通过钻孔延伸到脑中。头骨并包括多个端口。屏障可以覆盖压力传导导管的远端的端口，其中屏障和压力传导导管填充有多个气体分子，使得屏障在预定范围的ICP中不处于张紧状态。
