(57) **ABSTRACT**

According to a method of adaptive signal processing, compensation for deterioration of image quality caused by wave-front distortion is provided in an ultrasound imaging apparatus, with a low computing amount and with a precision. The elements **106** receive ultrasound signals from a test subject, and the delay circuit **204** delays each of the signals received by the plural elements in association with a predetermined position of a receive focus. The peripheral information operator **205** acquires from the post-delay received signals, information items as to plural points on the receive focus and in the peripheral region thereof, respectively. By way of example, the peripheral information operator obtains adaptive weights in association with plural steering angles. The peripheral information combiner **206** combines the plural information items (adaptive weights), and uses thus combined information to generate a beamforming output. Alternatively, the beamforming outputs are generated by using the plural adaptive weights and received signals, and thereafter, those outputs are combined.

ULTRASONIC IMAGING DEVICE

TECHNICAL FIELD

[0001] The present invention relates to an ultrasound imaging technique for imaging the inside of a test subject, through the use of ultrasound waves.

BACKGROUND ART

[0002] Ultrasound imaging is a technique for non-invasively creating an image of the inside of a test subject such as a human body, through the use of ultrasound waves (being a sound wave not intended for hearing, and generally a high-frequency sound wave having 20 kHz or higher). By way of example, a medical ultrasound imaging apparatus will be briefly explained. An ultrasound probe transmits the ultrasound waves to the inside of a patient body, and receives echo signals reflected from the inside of the patient. The received signals are subjected to signal processing in one or both of the ultrasound probe and the main unit of the ultrasound imaging apparatus, and thereafter transferred to a monitor, and then, an ultrasound image is displayed thereon. More specifically, for example, a transmit beamformer in the main unit of the ultrasound imaging apparatus generates signals of a transmission beam, allowing the signals to pass through the transmit-receive separation circuit (T/R), and thereafter transfers the signals to the ultrasound probe. The ultrasound probe sends out ultrasound waves. After receiving the echo signals from the internal body, the ultrasound probe transmits the signals to the main unit of the imaging apparatus. In the main unit of the imaging apparatus, the received signals pass through the transmit-receive separation circuit again, being subjected to beamforming process in the receive beamformer, and then those signals are transmitted to an image processor. The image processor executes various image processing through the use of various filters, a scan converter, and the like. Finally, the monitor displays an ultrasound image.

[0003] As described above, a general ultrasound diagnostic apparatus is made up of three techniques; transmit beamforming, receive beamforming, and a backend image processing. Particularly, since the beamformers for transmitting and receiving perform signal processing at an RF (high-frequency) level, algorithms and implementation architecture in the beamformers decide a basic image quality of the ultrasound image. Therefore, the beamformers serve as major parts of the apparatus.

[0004] The receive beamformer assigns a delay time to each received signal (received data) in plural elements that constitute the ultrasound probe, the delay time distributing an amount of delay in a concave form, in association with the relations between a focal position and the element positions, and after virtually achieving focus (focused) at a certain point in space, the received signal data items are summed up. This method is referred to as a beamforming according to a delay-and-sum method. In this delay-and-sum method, the received data items that are received by the plural elements in the ultrasound diagnostic apparatus are multiplied by a fixed weight vector stored in the diagnostic apparatus, then being weighted and summed up. This process is also performed in the transmit beamformer in a similar manner, not only in the receive beamformer.

[0005] On the other hand, as a basic problem of the ultrasound imaging apparatus, it is known that lateral resolution is subject to constraints. Since transmitting and receiving of the

ultrasound waves are performed by an array having a finite opening size, there is an impact of diffraction on the edge of the opening. If an infinitely long array is prepared, there is a possibility that the resolution is enhanced infinitely in the same manner as in the depth direction. In actual, however, a physical restriction in designing the apparatus, i.e., the length of the array, has hampered the enhancement of the lateral resolution. In recent years, it is attempted that the aforementioned fixed weight vector used for delaying, upon the delay-and-sum by the beamformer, is made to vary adaptively for the time-series transmit-receive data items, one by one, thereby obtaining an ultrasound image of higher definition, and this attempt is coming to attention. Accordingly, there is a possibility that this brings a marked improvement in the lateral resolution, being one of essential problems in the beamforming technique.

[0006] Particularly in recent years, an improved lateral resolution technique is being reported which is achieved by applying an adaptive signal processing technique including the MVDR method (Minimum Variance Distortionless Response; Capon method) that has been developed in the field of mobile communication, to the beamformer of the received data (Non Patent Documents 1 to 6). The technique described in those adaptive methods is implemented by adaptively varying complex components of the weight vector used for the delay-and-sum, on the basis of the correlative matrix of the received data. In other words, conventionally, the weight vector has been a fixed value, but in the adaptive method, the weight vector is obtained according to an operation with the use of the received signal, for each sample point in the time direction of the received signal, and the received signal is multiplied by thus obtained weight vector.

[0007] In the adaptive signal processing, similar to the conventional delay-and-sum method, distortion (aberration) of the ultrasound wavefront presents a significant challenge, the distortion being caused by inhomogeneous sound-velocity distribution in a medium and scattering from micro scatterers. Also in the adaptive signal processing, the apparatus sets the focus of the receive beamformer, assuming that the sound-velocity is constant and the medium is homogeneous. Therefore, when distortion exists in sound-wave propagation, there is a problem that an image appears blurred, or an image is formed on a position different from the actual position. In the conventional delay-and-sum method, correction of the wavefront distortion (wave aberration) is a long standing problem, and aberration correction technique utilizing cross-correlation processing has been studied. Also in the adaptive beamformer, it is a challenge to significantly change the image quality of an ultrasound image caused by inhomogeneity of the medium.

[0008] Following prior arts are known as describing techniques of a beamformer relating to the present invention; the Patent documents 1 to 3 regarding delay time adjustment using plural beams, the Patent document 4 regarding combined delay outputs, and the Patent document 5 regarding a technique for correcting wavefront distortion.

DISCLOSURE OF THE INVENTION

Problem to be Solved by the Invention

[0020] It is known that in an ultrasound diagnostic apparatus using an adaptive beamformer, beams are highly directive. However, actually, the medium of a test subject is inhomogeneous, and thus ultrasound signals being transmitted are reflected on a focus and scattered around the focus, resulting in that information regarding the object on the focus also

exists around the focus. Beams with high directivity from the adaptive beamformer are incapable of acquiring ultrasound signals that exist around the focus, and this may cause a problem that an image quality is deteriorated. Furthermore, since the medium of the test subject is inhomogeneous, there may occur wavefront distortion due to the sound-velocity inhomogeneity, or the like. The wavefront distortion may cause reflected waves from the medium surrounding the focus to mix into the received sound wave. The reflected waves from the surrounding medium may become a noise signal correlated with the information from the focus, and there is a problem that this correlative noise may deteriorate the image quality.

[0021] Therefore, there is required a technique which allows the focus information scattered around the focus to be reproduced, in compatible with reducing unnecessary correlative noise from the medium surrounding the focus. In other words, an adaptive beamforming technique is demanded, being able to reduce the number of the ultrasound signals failing to be picked up, after scattered around the focus, highly robust against the correlative noise caused by the wavefront distortion, and provided with an image-quality compensation method with relatively small processing load.

[0022] An object of the present invention is to provide an ultrasound imaging apparatus that is capable of compensating for the image-quality deterioration caused by inhomogeneity of the test subject medium.

Means to Solve the Problem

[0023] The ultrasound imaging apparatus of the present invention is provided with plural elements configured to receive ultrasound signals from a test subject, a delay unit configured to delay each of the received signals on the plural elements, in association with a position of a predetermined receive focus, and generate post-delay received signals, a peripheral information operator configured to acquire information items as to plural points within a region including the receive focus and a peripheral region thereof, respectively from the post-delay received signals, a peripheral information combiner configured to combine the information items acquired as to the plural points respectively, and generate a beamforming output by using the information being combined, and an image processor configured to use the beamforming output to generate image data.

Effect of the Invention

[0024] According to the present invention, it is possible to acquire ultrasound signals scattered around the focus, reduce of the number of the ultrasound signals failing to be picked up, achieve a highly robust property against the correlative noise caused by the wavefront distortion, and compensate for image-quality deterioration without significantly increasing the processing load.

[0051] FIG. 27 is a graph showing the intensity distribution of one point scatterer and surroundings thereof, with regard to the ultrasound images of FIG. 26.

MODES FOR CARRYING OUT THE INVENTION

[0052] Preferred embodiments of the present invention will be explained.

First Embodiment

[0053] The ultrasound imaging apparatus of the first embodiment is provided with plural elements configured to receive ultrasound signals from a test subject, a delay unit configured to delay each of the received signals on the plural elements, in association with a position of a predetermined receive focus and generate post-delay received signals, a peripheral information operator, a peripheral information combiner, and an image processor. The peripheral information operator acquires information items as to plural points within a region including the receive focus and the peripheral region of the receive focus, respectively from the post-delay received signals. The peripheral information combiner combines the information items respectively acquired as to the plural points, and uses the information being combined to generate a beamforming output. The image processor uses the beamforming output to generate image data. Specific explanations will be provided in the following.

[0054] Firstly, with reference to FIG. 1(a) and FIG. 1(b), an overall configuration of the ultrasound imaging apparatus will be explained. FIG. 1(a) is a perspective view of the apparatus, and FIG. 1(b) is a block diagram schematically showing the inner configuration.

[0055] As illustrated in FIG. 1(a), the ultrasound imaging apparatus is provided with an ultrasound probe 101, an apparatus main body 102, a monitor 103, and a console 110. As illustrated in FIG. 1(b), the apparatus main body 102 incorporates a transmit beamformer 104, a transmit-receive separation circuit (T/R) 107, a receive beamformer 108, an image processor 109, and a controller 111 for controlling operations of those described above.

[0056] The ultrasound probe 101 is provided with plural elements (ultrasound transducers) 106 arranged in the form of an array. The transmit beamformer 104 generates signals for a transmission beam, and transfers the transmission beam to the ultrasound probe 101 via the transmit-receive separation circuit 107. The ultrasound probe 101 transmits ultrasound waves from the plural elements, directed to the inside of the test subject 100. The ultrasound probe 101 receives echo signals reflected inside the body. The received signals go

through the transmit-receive separation circuit 107 again and subjected to beamforming operation, and the like, in the receive beamformer 108. The received signals after the beamforming operation is applied, are transferred to the image processor 109, and various image processes such as various filters, and a scan converter are executed on the received signals, and then, an ultrasound image is generated. The ultrasound image is transferred to the monitor 103, and displayed thereon.

[0057] FIG. 2 is a block diagram illustrating the configuration of the receive beamformer 108. As shown in FIG. 2, the receive beamformer 108 incorporates a delay circuit 204, a peripheral information operator 205, a peripheral information combiner 206, and a bypass line 207 from the output of the delay circuit 204 to the peripheral information combiner. Independent circuits may configure those components in the receive beamformer 108, respectively. It is alternatively possible to configure such that a memory storing programs in advance and a CPU for reading and executing the programs implement the operations of those components.

[0058] In the receive beamformer 108 of the present embodiment, under the control of the controller 111, the active channel setter (not illustrated) sets an active channel in a part of the finite aperture of the ultrasound probe 101, so as to perform the receive beamforming process. In other words, the elements 106 within a partial range are assumed as the active channel 201, among the plural elements 106 constituting the ultrasound probe 101 which has received echoes associated with one transmit ultrasound beam, and the receive beamformer generates one line of image data (raster: beamforming output $y(n)$) in the ultrasound propagating direction, by using the received signals in the active channel 201. As illustrated in FIG. 2, the positions of the elements 106 in the channel are displaced gradually, thereby sequentially configuring the active channel 202, active channel 201, and active channel 203, and the rasters are generated respectively for the active channels 202, 201, and 203. Resultant arrangement of the rasters forms an ultrasound image.

[0059] The delay circuit 204 corresponds to a block provided as a previous stage of the peripheral information operator 205, configured to give a delay time to each of the received signals (received data) on the plural elements 106 constituting the active channel 201, in association with the element position, so as to perform processing to focus the received signals on a certain point virtually existing in a space. The delay time given to each of the elements 106 is prepared in advance, as a delay-time set, in association with the object positions in the space of the imaging target. The delay circuit 204 selects the delay-time set in response to the focal position being set, and gives different delay times to the respective received signals on the plural elements. With this configuration, it is possible to perform the focusing process covering the entire space of the imaging target.

[0060] The peripheral information operator 205 performs the operation to collect information items that are scattered around the receive focus due to the reflection from the receive focus. By way of example, the peripheral information operator 205 performs the adaptive signal processing, thereby obtaining adaptive weights as to two or more points, on the receive focus and in its periphery (peripheral region). With this configuration, it is possible to collect peripheral information with respect to the receive focus. It is to be noted that the periphery (peripheral region) corresponds to an area where signals are scattered due to the reflection of the signals on the

receive focus, having a nearly elliptical shape (oval sphere in the three-dimensional case); the size being different depending on the conditions such as receive elements, a transmit frequency, a receive frequency, a ultrasound pulse waveform, the size and pitch of the element array, and a point spread function, roughly having a long axis spreading around $\pm 5^\circ$ or less in the active channel direction, assuming as the central axis, the axis connecting the receive focus and the center point of the active channel, and a short axis in a length equivalent to or a little shorter than the active channel direction, in the ultrasound propagating direction orthogonal to the active channel direction. On this occasion, the focus is positioned at an intersection of the short axis and the long axis. At the same time, the periphery (peripheral region) corresponds to an area where the wavefront distortion causes that the reflected waves from the medium surrounding the focus exist in the received waves in mixed manner, and the reflected waves from the surrounding medium may become obvious in the received signals in the form of noise signals, being correlated with the information from the focus.

[0061] The peripheral information combiner 206 combines (compounds) the peripheral information items collected by the peripheral information operator 205 and obtains a final beamforming output $y(n)$. By way of example, the peripheral information combiner 206 combines the adaptive weights of at least two points obtained by the peripheral information operator 205, and this combined weight being obtained is assigned on the signals of the elements 106, after the delay process is performed by the delay circuit 204, and weighted signals are subjected to beamforming, thereby combining the peripheral information items.

[0062] This finally obtained beamforming output $y(n)$ is sequentially transferred to the image processor 109, raster by raster, respectively in association with the active channels 202, 201, and 203, and an ultrasound image is generated on the basis of thus combined beamforming output.

[0063] As described above, in the first embodiment, the peripheral information operator 205 collects the information items from the surrounding of the receive focus, and even though the adaptive beamformer with high directivity is used, it is possible to collect the information items reflected on the focus, and scattered in the surrounding thereof. Furthermore, by using thus collected peripheral information, an asymmetry property of the correlative signals is utilized, and this cancels (performs decorrelation of) the correlative noise caused by the wavefront distortion. Therefore, even when the medium of the test subject is inhomogeneous, it is possible to prevent the image quality from being deteriorated, resisting the influence from the correlative noise caused by the wavefront distortion, thereby achieving a highly robust ultrasound imaging apparatus.

Second Embodiment

[0064] In the second embodiment, the peripheral information operator 205 in the ultrasound imaging apparatus of the first embodiment performs the adaptive beamforming, thereby obtaining an adaptive weight as information.

[0065] The peripheral information operator 205 obtains the adaptive weights as to plural points, by using steering vectors that are directional vectors connecting a predetermined position on a surface of the array made up of the plural elements 106 as described in the first embodiment, and the plural points.

[0066] Furthermore, the peripheral information operator **205** incorporates a matrix operator configured to generate a covariance matrix by using the post-delay received signals, and a weight vector operator configured to obtain adaptive weight vectors as to the plural points, from the steering vectors. The peripheral information combiner **206** incorporates a weight combiner configured to sum the adaptive weights as to plural points obtained by the peripheral information operator **205** and generate a combined weight, and an inner-product operator configured to multiply the post-delay received signals by the combined weight to generate a beamforming output.

[0067] It is further possible to arrange a fixed apodization multiplier between the peripheral information operator **205** and the weight combiner, the fixed apodization multiplier being configured to multiply each of the adaptive weights as to the plural points obtained in the peripheral information operator, by a fixed weight being predetermined.

[0068] The inner-product operator multiplies each of the post-delay received signals by the combined weight, and thereafter sums the post-delay received signals, so as to generate the beamforming output.

[0069] With reference to FIG. 3, the ultrasound imaging apparatus of the second embodiment of the present invention will be specifically explained. It is to be noted that a configuration similar to the first embodiment will not be tediously explained.

[0070] In the second embodiment, the peripheral information operator **205** obtains adaptive weights as to two or more points on the receive focus and in the periphery thereof, thereby collecting the peripheral information of the receive focus. Specifically, upon calculating the adaptive weight, plural steering vectors "a" are used so as to obtain the adaptive weight also as to a point at which the direction from the elements in the active channel of the ultrasound probe is displaced from the receive focus (i.e., a point at which the direction of the steering vector is different from the focus direction). The peripheral information combiner **206** combines the adaptive weights of two or more points obtained by the peripheral information operator **205**, and uses this obtained combined weight to perform beamforming process on the received signals. The steering vectors are directional vectors connecting the center position of the active channel and the points as described above. Details of the steering vectors will be explained with reference to the formula (4) described below. Hereinafter, more specific explanations will be given.

[0071] FIG. 3 is a block diagram illustrating a configuration of the receive beamformer **108** according to the second embodiment. Here, as a preferred embodiment of the present invention, there is illustrated an example to use an adaptive beamformer in which the adaptive signal processing technique is applied to the beamformer. It is to be noted here that the components other than the receive beamformer **108**, in other words, the ultrasound probe **101**, the transmit beamformer **104**, and the transmit-receive circuit **107**, being positioned in the previous stage of the receive beamformer **108**, and the image processor **109** and the monitor **103** being positioned in the subsequent stage of the receive beamformer **108**, are the same as those of the first embodiment. Therefore, tedious explanations and illustrations will not be given here.

[0072] As illustrated in FIG. 3, the peripheral information operator **205** in the receive beamformer **108** is provided with the matrix operator **300** and the adaptive weight operator **301**.

The adaptive weight operator **301** incorporates plural weight vector operators **3021**, **3022**, and **3023**, and computes the weight vectors respectively as to the receive focus and the points surrounding thereof. In this example here, three weight vector operators **3021** to **3023** are arranged, and thus it is possible to obtain the weight vectors as to three points. In the present embodiment, however, the number of the weight vector operators is not limited to three, and any number may be applicable, as far as it is more than one.

[0073] The matrix operator **300** receives inputs from the delay circuit **204** (post-delay received data $x(n)$), and generates the spatial covariance matrix $R(n)$. After inputted in the adaptive weight operator **301**, in each of the plural weight vector operators **3021**, **3022**, and **3023**, the spatial covariance matrix calculates weight vectors $w_1(n)$, $w_2(n)$, and $w_3(n)$, as to the predetermined three points with different steering vector directions, out of the points including the receive focus and in the periphery thereof, and outputs the calculated weight vectors to the peripheral information combiner **206**. Details of the steering vectors will be explained in the following.

[0074] The peripheral information combiner **206** is provided with the weight combiner **306** and the inner-product operator **307**. The weight combiner **306** sums the plural weight vectors $w_1(n)$, $w_2(n)$, and $w_3(n)$ to combine the vectors, and generates a combined weight $w_{sum}(n)$. The inner-product operator **307** uses this combined weight $w_{sum}(n)$ to assign weight on the post-delay received data $x(n)$ that is inputted via the bypass line **207**, and then sums the data to obtain the beamforming output $y(n)$. With this configuration, it is possible to obtain information in the form of one beamforming output, the information being acquired from the plural points within an identical raster and being different in the steering vector direction. Specifically the inner-product operator **307** incorporates a multiplier **3071** configured to multiply the post-delay received data $x(n)$ by the combined weight $w_{sum}(n)$, and an adder **3072** configured to calculate the sum of the post-delay data after the multiplication.

[0075] If needed, the fixed apodization multiplier **305** may be added to the peripheral information combiner **206**. The fixed apodization multiplier **305** multiplies the weight vectors $w_1(n)$, $w_2(n)$, and $w_3(n)$, by a predetermined fixed weight, so as to assign the weight on the weight vectors.

[0076] The beamforming output $y(n)$ obtained by the peripheral information combiner **206** is transferred to the image processor **109**. The image processor **109** generates an ultrasound image on the basis of the beamforming result $y(n)$.

[0077] In the following explanation, operations of each part will be explained in more detail, in the case where the received data is processed on each of the elements **106** in one active channel **201** in association with one-time transmission and receiving, so as to generate the beamforming data for one raster.

[0078] FIG. 4 illustrates the operations of the delay circuit **204**, including some other parts. Firstly, K elements **106** constituting the active channel **201** receive K pieces of data. Hereinafter, K pieces of the received data is also referred to as K -channel received data $u(n)$. The received data $u(n)$ passes through the transmit-receive separation circuit **107**, and enters the delay circuit **204**. The delay circuit **204** gives to the received signals (received data **404**) $u_1(n)$, $u_2(n)$, \dots , $u_K(n)$ of K elements **106** constituting the active channel **201**, delay time in such a manner as distributing the delay amount in the form of the concave shape **405** assuming one point **401** in the space as a center, in association with the positions of the

elements **106**, and then, obtains the post-delay received data $x_1(n), x_2(n), \dots, x_K(n)$. With this configuration, the focus **401** is virtually obtained. Here, “n” represents a certain time (snapshot time) in the time direction (the depth direction in the ultrasound propagating direction) of the ultrasound received signal. When the total number of samples in one raster is assumed as N, it is in the range of $0 < n < (N+1)$. By shifting this snapshot time n, and also changing the concave shape **405** to a different concave shape (e.g., concave shapes **406** and **407**), each of the focuses **402** and **403** is allowed to be obtained. With this configuration, the received signal **404** on each element **106** is delayed, focusing on a desired point, and time-series data items **408**, **409**, and **410** of the received signals (post-delay received data) with aligned wavefront are obtained.

[0079] If the number of the elements constituting the active channel **201** (the number of channels) is K, it is possible to express K post-delay received data items at a certain snapshot time n, as the vector $x(n)$ on the left-hand side of the following formula (1).

[Formula 1]

$$x(n) = [x_1(n), x_2(n), \dots, x_K(n)]^T \quad (1)$$

[0080] In the adaptive beamformer according to a conventional technique, this post-delay received data $x(n)$ is inputted in the adaptive processor, so as to generate adaptive weight vector $w(n) = [w_1(n), w_2(n), \dots, w_K(n)]^T$ being made up of weight values $w_k(n)$ for the respective K channels at the snapshot time n. Furthermore, this adaptive weight vectors $w(n)$ and the post-delay received data $x(n)$ are subjected to an inner-product operation in the inner-product operator, and the adaptive beamformer output $y(n)$ at a certain snapshot time n is obtained. In the present invention, plural steering vectors “a” are used to obtain the adaptive weight vectors also for the periphery of the focal position.

[0081] As illustrated in FIG. 3, the post-delay received data vectors $x(n)$ are inputted in the peripheral information operator **205**. In the peripheral information operator, the matrix operator **300** firstly obtains the spatial covariance matrix $R(n)$ according to the formula (2). Upon obtaining $R(n)$, $x(n)$ may be used as a real signal as it is, or it may be subjected to Hilbert transform or baseband modulation, so as to use the resultant complex data after the conversion. Here, a more general example will be explained, taking an example that $x(n)$ is converted to complex data (n), and the spatial covariance matrix $R(n)$ is obtained as expressed by the formula (2). $R(n)$ in the formula (2) indicates an ensemble average of a product of the complex vector $\xi(n)$ expressed by the formula (3) and its (complex) conjugate transpose vector $\xi^H(n)$.

[Formula 2]

$$R(n) = E[\xi(n)\xi^H(n)] \quad (2)$$

$$= E \left[\begin{pmatrix} \xi_1(n)\xi_1^*(n) & \xi_1(n)\xi_2^*(n) & \dots & \xi_1(n)\xi_K^*(n) \\ \xi_2(n)\xi_1^*(n) & \xi_2(n)\xi_2^*(n) & \dots & \xi_2(n)\xi_K^*(n) \\ \vdots & \vdots & \ddots & \vdots \\ \xi_K(n)\xi_1^*(n) & \xi_K(n)\xi_2^*(n) & \dots & \xi_K(n)\xi_K^*(n) \end{pmatrix} \right]$$

$$= \frac{1}{N} \sum_{s=-S}^S \xi(n+s)\xi^H(n+s)$$

-continued

[Formula 3]

$$\xi(n) = [\xi_1(n), \xi_2(n), \dots, \xi_K(n)]^T \quad (3)$$

[0082] In the formula (2), the ensemble average number N may indicate as a uniform mean as shown on the rightmost side of the formula (2), assuming the total number of samples before and after $\xi(n)$ of the target snapshot as $N=2S+1$ points. Another method for averaging in the time direction may be taken, the method multiplying each sample in the time direction by an arbitrary weight, such as a trapezoidal weight, and calculating the arithmetic mean. The spatial covariance matrix $R(n)$ outputted from the matrix operator **300** is subsequently inputted into the adaptive weight operator **301**.

[0083] The adaptive weight operator **301** that has received the spatial covariance matrix $R(n)$ calculates weight vectors $w(n)$ according to the MVDR method. In the present invention, plural steering vectors “a” are used to obtain the peripheral information of the focus. The steering vectors a_p is expressed by the formula (4).

[Formula 4]

$$a_p = \begin{bmatrix} \exp\{j\psi_1(\theta_p, \phi_p, f_p)\}, \exp\{j\psi_2(\theta_p, \phi_p, f_p)\}, \dots, \\ \exp\{j\psi_K(\theta_p, \phi_p, f_p)\}, \\ 1, \exp\left(-j\frac{2\pi}{\lambda_p} d \sin\theta_p\right), \exp\left(-j\frac{2\pi}{\lambda_p} \cdot 2d \sin\theta_p\right), \dots \\ \exp\left(-j\frac{2\pi}{\lambda_p} (K-1)d \sin\theta_p\right) \end{bmatrix} \quad (4)$$

[0084] In the above formula (4), “p” represents the number of the steering vectors, and it is an integer satisfying $0 < p < P+1$, when the total number is assumed as P. As shown in the formula (4), the steering vectors a_p is a directional vector having K vector elements (from 0 to (K-1)), the number being equal to the number of the active channels. The steering vector is expressed by a function of the receive frequency f_p and the angle (θ_p, ϕ_p) formed by the normal vector direction on the surface of the elements **106** and the steering vector (hereinafter, referred to as “steering angle”). Here, “ θ_p ” represents an aperture angle from the normal vector, and “ ϕ_p ” represents a swivel angle from the array direction of the elements **106**. When the array of the elements **106** in the ultrasound probe **101** is a one-dimensional (linear) array, the steering angle is expressed by the final form of the formula (4). Here, “ λ_p ” represents a wavelength of a sound wave associated with the frequency f_p , and “d” represents a distance between the center of the elements **106** (pitch between the elements).

[0085] The weight vector $w(n)$ obtained by the MVDR method, as to the direction of the steering vector a_p as described above is calculated by the formula (5) in this example. Therefore, the weight vectors $w(n)$ are computed as to the steering vectors a_p being different respectively in the weight vector operators **3021** to **3023**, thereby obtaining the adaptive weight vectors $w_1(n)$ to $w_P(n)$ corresponding to the number P of the steering vectors a_p (i.e., the number of the weight vector operators **3021** to **3023**).

[Formula 5]

$$w_p(n) = \frac{R^{-1}(n)}{a_p^H R^{-1}(n) a_p} \quad (5)$$

In the formula (5), $R(n)$ represents the spatial covariance matrix at a certain snap shot n in the time direction, being generated by the formula (2), and the superscript “-1” represents an inverse matrix.

[0086] It is to be noted that the number P of the steering vectors may be any value, as for as it is an integer at least two. Any method for selecting the direction of the steering vector is applicable. In the present embodiment, it is assumed that the focus is positioned on the central axis of the channel **201**; i.e., if the number of the active channels is an even number, it is positioned on the normal line (the normal line is orthogonal to the active channel surface) passing through the middle point between the $K/2^{th}$ and the $(K+2)/2^{th}$ elements, out of the K elements **106** constituting the active channel **201**. If the number of the active channels is an odd number, it is assumed that the focus is positioned on the normal line (the normal line is orthogonal to the active channel surface) passing through the center of the $(K+1)/2^{th}$ element, out of the K elements constituting the active channel **201**. It is desirable that one of the steering vectors faces the focus direction. Another $(P-1)$ steering vectors are configured in such a manner as facing any directions within the region surrounding the focus in the imaging space. FIG. 3 illustrates the case where the total number of the steering vectors $P=3$, but the total number of the steering vectors may be any number. The steering angle thereof may be for instance, at an equiangular pitch, or conform to a non-linear rule, or any irregular and random method may be taken for selecting the angle. By way of example, the configuration of FIG. 3 illustrates the case where $P=3$, and the number of the weight operator outputs is three; that is, $w_1(n)$, $w_2(n)$, and $w_3(n)$.

[0087] As described above, since the delay process is performed in the delay circuit **204**, the received data vector $x(n)$, for instance, at a certain clock time n in the linear scanning becomes data with aligned wavefronts in the direction of $\theta=0^\circ$ being the direction of the normal vector. Therefore, in the formula (4), if it is assumed that $\theta_p=0^\circ$, the steering vectors a_p are equal to $[1, 1 \dots 1]^T$, and the adaptive weight vector $w(n)$ in the focus direction is obtained. The adaptive weight vector $w(n)$ in the focus direction corresponds to the adaptive weight vector $w(n)$ obtained by the conventional MVDR method. In other words, if it is assumed that $P=1$ and $\theta_p=0^\circ$ in the configuration of the present embodiment, it corresponds to the configuration of the adaptive beamformer using an ordinary MVDR method. The beamformer according to the present embodiment is different from the beamformer according to the ordinary MVDR method, in the point that various plural steering vectors a_p are set, and adaptive weight vectors $w_1(n)$ to $w_p(n)$ are obtained for the respective vectors.

[0088] The present invention is not limited to the configuration that one of the plural steering vectors a_p faces the focus direction (front direction) ($\theta_p=0^\circ$, $a_p=[1, 1 \dots 1]^T$), but all the steering vectors may face the directions different from the focus direction. In particular, as a direction vector constituting the plural steering vectors a_p , the direction vector in the focus direction ($\theta_p=0^\circ$) is not used on purpose, and only the direction vector in the direction ($\theta_p < 0^\circ$, $0^\circ < \theta_p$) excluding the

focus direction may be used. In this situation, the focus direction is not used on purpose, and this enhances the effect of the correlative noise canceling (decorrelation) more. Therefore, it is one of the preferred embodiments of the present invention.

[0089] The P adaptive weight vectors $w_1(n)$ to $w_p(n)$ outputted from the adaptive weight operator **301** are inputted into the peripheral information combiner **206**. The peripheral information combiner **206** sums the P adaptive weight vectors $w_1(n)$ to $w_p(n)$ in the weight combiner **306**, takes an arithmetic average, and calculate the combined weight vector $w_{sum}(n)$ as shown in the formula (6). By way of example, as shown in FIG. 3, the combined weight vector $w_{sum}(n)$ of the adaptive weight vectors when $P=3$, are obtained as $w_{sum}(n) = \{w_1(n) + w_2(n) + w_3(n)\}/3$.

[Formula 6]

$$w_{sum}(n) = \sum_{p=1}^P w_p(n) \quad (6)$$

$$= \frac{1}{P} \{w_1(n) + w_2(n) + \dots + w_p(n) \dots + w_p(n)\}$$

[0090] It is to be noted that in the stage prior to obtaining the combined weight vector $w_{sum}(n)$, a fixed apodization multiplier **305** may be provided, so as to multiply each of the weight vectors $w_p(n)$ by a fixed apodization. By way of example, it is possible to multiply the weight vectors by the fixed apodization by having a distribution where a value of the adaptive weight vector $w_p(n)$ in the direction of $\theta=0^\circ$ is made larger and values in another directions are made smaller, and this is implemented by the computation as shown in the formula (7).

[Formula 7]

$$w_{sum}(n) = \sum_{p=1}^P b_p w_p(n) \quad (7)$$

$$= \frac{1}{P} \{b_1 w_1(n) + b_2 w_2(n) + \dots + b_p w_p(n) \dots + b_p w_p(n)\}$$

[0091] By way of example, in the configuration of FIG. 3, there are prepared fixed apodization weights b_1 , b_2 , and b_3 in the fixed apodization multiplier **305**. In this situation, the combined weight outputted from the weight combiner becomes $w_{sum}(n) = \{b_1 w_1(n) + b_2 w_2(n) + b_3 w_3(n)\}/3$.

[0092] Next, the combined weight vector $w_{sum}(n)$ is inputted into the inner-product operator **307** within the peripheral information combiner **206**. The inner-product operator **307** incorporates the multiplier **3071** and the adder **3072**, performs the inner-product operation between the combined weight vector $w_{sum}(n)$ and the received data vectors $x(n)$ transferred from the delay circuit **204** via the bypass line **207**, as shown in the formula (8), and then obtains the beamforming output $y(n)$. Specifically, the multiplier **3071** obtains the product of the weight vector and each channel element of the post-delay received data vectors (1 to K). The adder **3072** calculates a total sum of the K products obtained by the

multiplier **3071**, and obtains a final output of the peripheral information combiner **206** (beamforming output $y(n)$, scalar value).

[Formula 8]

$$y(n) = w_{sum}^H(n) \times x(n) \quad (8)$$

[0093] This beamforming output $y(n)$ from the inner-product operator **307** is transferred to the image processor **109**. The processing above is repeated for the N samples constituting one raster, from the first sample $n=1$ to the final sample $n=N$, and then, N beamforming outputs $y(n)$; $y(1)$, $y(2)$. . . $y(N)$, are transferred sequentially to the image processor **109**. Consequently, the receive beamformer **108** completes the computations of the beamforming outputs $y(n)$ for one raster in association with the active channel **201**.

[0094] The beamforming outputs $y(n)$ for one raster obtained by the formula (8), are acquired respectively for the active channels, shifting on the received array from the active channel **201** to the active channels **202**, and **203**, and transferred to the image processor **109**, raster by raster. In the image processor **109**, a scan converter associated with the scanning system of the ultrasound probe **101**, arranges all the rasters and generates a two-dimensional image. In addition, backend image processing such as various filter processing, and computations by measurement applications are performed. Finally the monitor **103** displays an ultrasound image and a computational result of the measurement applications.

[0095] As described above, in the second embodiment, plural steering vectors a_p are set, and the adaptive weight vectors $w_1(n)$ to $w_p(n)$ are obtained for the respective steering vectors, and combined weight vector $w_{sum}(n)$ obtained by combining those adaptive weight vectors is used to perform beamforming of the received data vectors $x(n)$. Then, one beamforming output $y(n)$ is obtained. With reference to FIG. 5 and FIG. 6, the effect will be explained.

[0096] FIG. 5(a) illustrates an example that data is received once from the active array **201**, focusing on the receive focus **2201**, and the receive beamforming is performed. When the receive beamforming is performed according to the conventional delay-and-sum method, signals in the region indicated by the point spread function **2202** around the receive focus **2201** may also be acquired by one-time receive beamforming. On the other hand, when adaptive beamforming is performed for this case, since the beam directivity is higher than the delay-and-sum method, the range of the signals being obtained by one-time receive beamforming is represented by the point spread function **2204**, and it is smaller than the range represented by the point spread function **2202** of the delay-and-sum method. Here, it is conceivable that the signals of the object on the focus **2201** are reflected by the focus **2201** and distributed randomly in the periphery of the focus **2201** as indicated by the elliptic region **2205**. This elliptic region **2205** corresponds to the periphery (peripheral region) of the first embodiment.

[0097] In the second embodiment, as described above, the adaptive weight vectors obtained by the adaptive beamformer, as to the respective plural points (here three points) having different steering angles are combined. This process is equivalent to allow the regions of the point spread function **2204** to overlap one another, the regions corresponding to the respective peripheries of the plural points as shown in FIG. 5(b). Therefore, in the second embodiment, the region **2206** obtained by the three displaced regions of the point spread function **2204** overlapping one another become the region

allowing the signals therein to be acquired by one-time receiving. Therefore, it is possible to acquire most of the signals of the object, scattered in the elliptic region **2205** surrounding the focus **2201**, and this allows reduction of the number of signals failing to be picked up.

[0098] By using the weight vectors having different steering angles, it is possible to utilize an asymmetry property of noise on the right side and noise on the left side of the central axis, being correlated with each other. In other words, adaptive weights having different steering angles are combined, thereby canceling (performing decorrelation of) the correlative noise signals in the received signals, and therefore, it is possible to selectively eliminate highly correlative noise signals, without failing to pick up the information of the signals on the focus.

[0099] According to the second embodiment, the effects as described above bring about improvements against the disadvantages such as; failing to pick up signals due to the sharp beam directivity of the adaptive beamformer, and being vulnerable to influence of the wavefront distortion. Therefore, this provides robustness, being impervious to such influence.

[0100] In the second embodiment, as shown in FIG. 6, the receive beamforming is performed every receiving (raster by raster). This may reduce the noise included in the beamforming outputs **1504**, **1505**, and **1506** respectively from the rasters **1501**, **1502**, and **1503**, and attenuate the impact of the wavefront distortion. Therefore, an ultrasound image obtained by arranging those beamforming outputs of the respective rasters is a clear image with less noise, and with reduced impact of wavefront distortion caused by the influences such as sound-velocity inhomogeneous in the living body, a scatterer distribution, and body motion.

[0101] In the second embodiment, it is alternatively possible to perform spatial average operation using a subarray matrix, as one of other methods of the arithmetic algorithm in the aforementioned matrix operator **300**. The subarray matrix \hat{R}_{SUBI} in the spatial average operation is expressed by a product of the subspace vectors $\hat{\xi}_l(n)$ (Formula (10)) as shown in the formula (9). The subspace vector $\hat{\xi}_l(n)$ is a vector obtained by extracting a partial substance (L elements) from the post-delay received data (that is represented by generalized complex signal vector $\hat{\xi}(n)$ here, but that may also be represented by a real vector $x(n)$, instead) in association with K active channels. Therefore, the total number of the subspace vectors is equal to $(K-L+1)$ ($0 < L$ (L is lower case of L) $< (K-L+1)$).

[Formula 9]

$$\hat{R}_{SUBI}(n) = \hat{\xi}_l(n) \hat{\xi}_l^H(n) \quad (9)$$

[Formula 10]

$$\hat{\xi}_l(n) = [\hat{\xi}_l(n), \hat{\xi}_{l+1}(n), \dots, \hat{\xi}_{l+L-1}(n)]^T \quad (10)$$

[0102] Samples are displaced one by one, establishing association between the main diagonal component of this subarray matrix and the main diagonal component of the spatial covariance matrix $R(n)$, resulting in a spatial averaging process of the $(K-L+1)$ subarray matrixes, and the subarray spatial covariance matrix $\hat{R}(n)$ as shown in the formula (11) is obtained. When the adaptive weight operator **301** computes the subarray spatial covariance matrix $\hat{R}(n)$, it is used to substitute for $R(n)$ in the above formula (5), and weight vectors $w_p(n)$ is computed as shown in the formula (12). It is to be noted that the output from the matrix operator

300 for this case is $(L \times L)$ in size, and the number of the elements constituting the weight vectors $w_p(n)$ becomes L .

[Formula 11]

$$\begin{aligned} R^{\wedge}(n) &= \frac{1}{N(K-L+1)} \sum_{s=-S}^S \sum_{l=1}^{K-L+1} R_{SUBI}^{\wedge}(n) \\ &= \frac{1}{N(K-L+1)} \sum_{s=-S}^S \sum_{l=1}^{K-L+1} \xi_l^{\wedge}(n) \xi_l^{\wedge H}(n) \end{aligned} \quad (11)$$

[Formula 12]

$$w_p(n) = \frac{R^{\wedge-1}(n)}{a_p^H R^{\wedge-1}(n) a_p} \quad (12)$$

[0103] As another alternative example of the spatial averaging method, a forward and backward spatial averaging method may be employed. In this situation, the backward subarray matrix $R_{SUBI}^{\sim}(n)$ may be obtained by a product of the backward subspace vector $\xi_l^{\sim}(n)$ as shown in the formula (13). The backward subspace vector is expressed by the formula (14). According to the computation similar to the forward spatial averaging, the backward subarray spatial matrix $R^{\sim}(n)$ may be calculated as shown in the formula (15). Next, as shown in the formula (16), it is subjected to the arithmetic averaging together with the subarray spatial matrix $R^{\wedge}(n)$ for the case of the aforementioned forward spatial averaging, and finally the forward and backward subarray spatial covariance matrix $R_{FB}(n)$ may be obtained. Similar to the forward spatial averaging, this forward and backward subarray spatial covariance matrix $R_{FB}(n)$ is substituted for $R(n)$ in the formula (5) in the computations in the adaptive weight operator **301**, thereby computing the weight vectors $w_p(n)$ as shown in the formula (17). Also in this case, the output from the matrix operator **300** is $(L \times L)$ in size, and the number of elements constituting the weight vectors $w_p(n)$ is L .

[Formula 13]

$$R_{SUBI}^{\sim}(n) = \xi_l^{\sim}(n) \xi_l^{\sim H}(n) \quad (13)$$

[Formula 14]

$$\xi_l^{\sim}(n) = [\xi_{K-l-1}(n), \xi_{K-l-2}(n), \dots, \xi_{K-l-K}(n)]^T \quad (14)$$

[Formula 15]

$$\begin{aligned} R^{\sim}(n) &= \frac{1}{N(K-L+1)} \sum_{s=-S}^S \sum_{l=1}^{K-L+1} R_{SUBI}^{\sim}(n) \\ &= \frac{1}{N(K-L+1)} \sum_{s=-S}^S \sum_{l=1}^{K-L+1} \xi_l^{\sim}(n) \xi_l^{\sim H}(n) \end{aligned} \quad (15)$$

[Formula 16]

$$R_{FB}(n) = \frac{R^{\wedge}(n) + R^{\sim}(n)}{2} \quad (16)$$

[Formula 17]

$$w_p(n) = \frac{R_{FB}^{-1}(n)}{a_p^H R_{FB}^{-1}(n) a_p} \quad (17)$$

[0104] Plural (P) weight vectors w_p calculated in the formula (12) or in the formula (17) according to the spatial averaging method are transferred to the peripheral information combiner **206**, similar to the case where the spatial averaging method is not employed. The weight combiner **306** sums the weight vectors, and calculates w_{sum} (Formula (7), Formula (8)). Furthermore, the inner-product operator **307** performs the inner product calculation using the post-delay received data transferred via the bypass line **207**, and eventually, the result is transferred to the image processor **109** as the beamforming data $y(n)$.

[0105] In this example, the spatial averaging method is used under the condition that the number of the elements of the weight vectors w_p is L . Therefore, in order to perform computations finally in the inner-product operator **307**, a block is additionally required, so as to perform the computation that generates vectors $g(n)$ having L components, out of (n) having K components (Formula (18)). For example, as shown in FIG. 3, a dimensional compressor **308** may be arranged in the middle of the bypass line **207** and also in the previous stage of the inner-product operator **307**, allowing the dimensional compressor **308** to generate the vectors $g(n)$ having L elements, from (n) having K elements. It is to be noted that the dimensional compressor **308** may be arranged within the peripheral information combiner **206**.

[0106] The beamforming output $y(n)$ using the spatial averaging method is expressed by the formula (19).

[Formula 18]

$$g(n) = \sum_{l=1}^{K-L+1} \xi_l^{\wedge}(n) \quad (18)$$

[Formula 19]

$$y(n) = w_{sum}^H(n) g(n) \quad (19)$$

[0107] As described above, the matrix operator **300** performs the spatial averaging process using the subarray matrix, and produces an effect that restrains correlated noises being included in the received ultrasound signals. Therefore, the spatial averaging process using the subarray matrix is combined with the configuration for synthesizing plural adaptive weight vectors around the focus, thereby obtaining an ultrasound image that is much less influenced by noise.

[0108] In the second embodiment as described above, the MVDR is taken as an example for explaining the adaptive beamforming method. However, the algorithm applied in the adaptive weight operator **301** may be any other algorithm as far as it uses the spatial covariance matrix calculated in the matrix operator **300**. Any other methods may be applicable, such as the MMSE method, APES method, Eigenspace-MV method (ESMV, EIBMV) using the spatial covariance matrix and its eigenvalues and eigenvectors, ESPRIT method, and MUSIC method.

Third Embodiment

[0109] The third embodiment is different from the second embodiment in the point that the peripheral information combiner **206** multiplies the post-delay received signals, by the adaptive weights respectively for the plural points obtained by the peripheral information operator **205**, and plural inner-

product operators for generating pre-synthesis beamforming outputs respectively for the plural adaptive weights, and an output combiner are provided. The output combiner sums and combines the pre-synthesis beamforming outputs respectively as to the plural adaptive weights, and generates a beamforming output to be used for generating image data.

[0110] It is further possible to arrange between the peripheral information operator **205** and plural inner-product operators, a fixed apodization multiplier configured to multiply the adaptive weights for the respective plural points obtained by the peripheral information operator **205**, by fixed weights being predetermined respectively. It is alternatively possible to arrange between the plural inner-product operators and the output combiner, the fixed apodization multiplier configured to multiply the plural post-delay received signals for the respective adaptive weights, by the fixed weights being predetermined respectively. It is further alternatively possible to arrange between the plural multipliers and the plural adders constituting the plural inner-product operators, the fixed apodization multiplier configured to multiply the plural signals after multiplication, by fixed weights being predetermined respectively.

[0111] The peripheral information combiner **206** combines the information items that is obtained by the peripheral information operator **205** from the received signals in one active channel, and generates a final beamforming output that is used by the image processor to generate an image. By way of example, the peripheral information combiner **206** sums the pre-synthesis beamforming outputs for the respective plural adaptive weights, obtained by the peripheral information operator **205** from the received signals in one active channel, and generates a final beamforming output that is used by the image processor **109** with respect to each active channel, so as to generate an image.

[0112] With reference to FIG. 7, the ultrasound imaging apparatus according to the third embodiment of the present invention will be explained specifically. In the third embodiment, since only the configuration of the peripheral information combiner **206** is different from the second embodiment, only the different part will be explained without tediously explaining the remaining parts.

[0113] In the second embodiment as shown in FIG. 3, the peripheral information combiner **206** combines the plural adaptive weight vectors $w_1(n)$, $w_2(n)$, and $w_3(n)$ by the weight combiner **306**, and with the use of thus obtained combined weight $w_{sum}(n)$, the beamforming summation process is performed on the post-delay received data $x(n)$. Since this is a linear operation, processing of the weight combining and processing of the beamforming summation may be transposed. The plural inner-product operator **307** of the third embodiment, as shown in FIG. 7, incorporates the plural multipliers (**3071-1**, **3071-2**, and **3071-3**), and the plural adders **3072-1**, **3072-2**, and **3072-3** configured to calculate the sum of the elements after the multiplication (post-delay data) to obtain the pre-synthesis beamforming output, respectively for the plural adaptive weight vectors $w_1(n)$, $w_2(n)$, and $w_3(n)$. A set of one multiplier **3071** and one adder **3072** configures one inner-product operator for each of the adaptive weight vectors. Preparing this set more than one configures plural inner-product operators **307**.

[0114] The post-delay received data $x(n)$ is inputted in the multipliers **3071-1**, **3071-2**, and **3071-3**, respectively via the

bypass inputs **2071**, **2072**, and **2073**. The output combiner **500** is arranged in the subsequent stage of the plural inner-product operators **307**.

[0115] With this configuration, in the plural inner-product operators **307**, the bypass input **2071** is subjected to the beamforming summation by using the weight vectors $w_1(n)$, the bypass input **2072** is subjected to the beamforming summation by using the weight vectors $w_2(n)$, and the bypass input **2073** is subjected to the beamforming summation by using the weight vectors $w_2(n)$. Then, plural pre-synthesis beamforming outputs $y_1(n)$, $y_2(n)$, and $y_3(n)$ respectively in association with the steering vectors are calculated (Formula (20) in the following). In the output combiner **500** in the subsequent stage, arithmetic averaging of the beamforming outputs $y_1(n)$, $y_2(n)$, and $y_3(n)$ respectively associated with the steering vectors is calculated, and the combined beamforming output $y_{sum}(n)$ is obtained as shown in the formula (21).

[Formula 20]

$$y_p(n) = w_p^H(n)x(n) \quad (20)$$

$$y_{sum}(n) = \sum_{p=1}^P y_p(n) = \frac{1}{P} \{y_1(n) + y_2(n) + \dots + y_p(n) \dots + y_P(n)\} \quad (21)$$

[0116] As illustrated in FIG. 7, also in the present embodiment, the fixed apodization multiplier **305** may be added. In FIG. 7, the fixed apodization multiplier **305** is placed in the previous stage of the inner-product operator **307**. However, the position of the fixed apodization multiplier **305** is not limited to the place as shown in FIG. 7. Since the operation is a linear operation, it is obviously possible to add the fixed apodization multiplier **305** between the inner-product operator **307** and the output combiner **500**, or to add the fixed apodization multiplier **305** between the multipliers **3071-1** to **3071-3** and the adders **3072-1** to **3072-3** in the inner-product operator. In any of the above cases, the final combined beamforming output $y_{sum}(n)$ is expressed by the formula (22).

[Formula 22]

$$y_{sum}(n) = \sum_{p=1}^P b_p y_p(n) = \frac{1}{P} \{b_1 y_1(n) + b_2 y_2(n) + \dots + b_p y_p(n) \dots + b_P y_P(n)\} \quad (22)$$

[0117] As described above, the second embodiment is different from the third embodiment in the point that the weights are combined and thereafter the inner-product operation is performed; or the beamforming outputs after the inner-product operation are combined. On the other hand, the final output is identical since this is a linear operation, and $y(n)$ in the formula (19) being the final beamforming output of the second embodiment becomes a value being equal to the final combined beamforming output $y_{sum}(n)$ of the third embodiment.

Fourth Embodiment

[0118] In the fourth embodiment, the delay unit (delay circuit **204**) generates post-delay received signals respectively for different plural receive focuses. The peripheral

information operator **205** and the peripheral information combiner **206** acquire information items as to the receive focus and plural points in the periphery of the receive focus, as to each of the plural receive focuses, and generates a beamforming output. By way of example, the delay unit (delay circuit **204**) is prepared more than one, and generates the post-delay received signal as to each of the receive focuses being different for the plural delay units, respectively. The peripheral information operator **205** and the peripheral information combiner **206** are arranged for each of the delay units, acquire information from the post-delay received signal generated by the delay unit for each receive focus, and generates the beamforming output.

[0119] On this occasion, the positions of the plural receive focuses of the received signals in the active channel at a certain point of time, may partially overlap the positions of the plural receive focuses for the active channel at a different point of time.

[0120] With reference to FIG. **8** to FIG. **10**, the ultrasound imaging apparatus according to the fourth embodiment of the present invention will be specifically explained. The configurations similar to the second and the third embodiments may not be tediously explained, and only the different portions will be explained.

[0121] In the second and the third embodiments, explanations are provided for the case that the focus is positioned on the central axis (the normal line passing through the active channel center, with respect to the active channel surface) for every received signal. In the fourth embodiment, as illustrated in FIG. **8**, plural points are set as the focuses at a certain depth for every received signal. By way of example, the focuses are set respectively on the points **601** and **603** on the axes in proximity to and displaced from the central axis **1600**, on both sides of the point **602** on the central axis, and information of the test subject **100** is collected. Configuring a distribution of the delay times of the received signals of the K elements **106** constituting the active channel, in the form of concave **604**, **605**, and **606** respectively centering on the focus **601**, **602**, and **603**, allows the signals received for one time, to focus on the plural focuses **601**, **602**, and **603**.

[0122] In the present embodiment, the post-delay data obtained as to each of the plural focuses **601**, **602**, **603** at a certain depth (at a certain snapshot time n) is subjected to arithmetic operation for collecting and combining the periphery information.

[0123] FIG. **9** is a block diagram illustrating the receive beamformer **108** according to the fourth embodiment. As shown in FIG. **8**, in the present embodiment, in order to set plural focuses **601**, **602**, and **603** simultaneously at a certain snapshot time, the receive beamformer **108** is provided with the delay circuits **2041**, **2042**, and **2043**, the peripheral information operators **2051**, **2052**, and **2053**, and the peripheral information combiners **2061**, **2062**, and **2063**, the number of which is the same as the number of the focuses. The configurations of the peripheral information operators **2051**, **2052**, and **2053**, and the peripheral information combiners **2061**, **2062**, and **2063** are the same as those of the peripheral information operator **205** and the peripheral information combiner **206** in the second embodiment. Therefore, the number of the beamforming outputs $y(n)$ is equal to the number of the focuses, and in the example of FIG. **9**, there are three beamforming outputs, $y_1(n)$, $y_2(n)$, and $y_3(n)$.

[0124] The signal processing operations of the fourth embodiment will be explained. The delay circuit **2042** forms

a delay concave surface to obtain the focus **602** on the central axis **1600** of the active channel at a certain snapshot time n , the delay circuits **2041** and **2043** form the delay concave surfaces respectively for obtaining the focuses **601** and **603** on the axes displaced from the central axis **1600**, and then the delay circuits generate the post-delay received data.

[0125] As shown in FIG. **10(a)**, the peripheral information combiner **2051** performs the operations as explained in the second embodiment, on the post-delay received data from the delay circuit **2041**, so as to calculate the weight vectors $w_{1_1}(n)$, $w_{1_2}(n)$, and $w_{1_3}(n)$ respectively for the focus **601** and two points forming the steering angle **1602** with respect to the direction of the focus **601**. The peripheral information combiner **2061** combines the weight vectors $w_{1_1}(n)$, $w_{1_2}(n)$, and $w_{1_3}(n)$, and then uses thus combined weight vector $w_{1_{sum}}(n)$ to obtain the beamforming output $y_1(n)$.

[0126] As shown in FIG. **10(b)**, the peripheral information combiner **2052** performs operations on the post-delay received data from the delay circuit **2042**, and calculates the weight vectors $w_{2_1}(n)$, $w_{2_2}(n)$, and $w_{2_3}(n)$ respectively for the focus **602** and the two points forming the steering angle **1604** with respect to the direction of the focus **602**. The peripheral information combiner **2062** combines the weight vectors $w_{2_1}(n)$, $w_{2_2}(n)$, and $w_{2_3}(n)$, so as to use thus combined weight vector $w_{2_{sum}}(n)$ to obtain the beamforming output $y_2(n)$.

[0127] Similarly, as shown in FIG. **10(c)**, the peripheral information combiner **2053** performs operations on the post-delay received data from the delay circuit **2043**, and calculates the weight vectors $w_{3_1}(n)$, $w_{3_2}(n)$, and $w_{3_3}(n)$ respectively for the focus **603** and the two points forming the steering angle **1606** with respect to the direction of the focus **603**. The peripheral information combiner **2063** combines the weight vectors $w_{3_1}(n)$, $w_{3_2}(n)$, and $w_{3_3}(n)$, and uses thus combined weight vector $w_{3_{sum}}(n)$ to obtain the beamforming output $y_3(n)$.

[0128] Those beamforming outputs $y_{1_{sum}}(n)$, $y_{2_{sum}}(n)$, and $y_{3_{sum}}(n)$ are transferred to the image processor **109**.

[0129] The processing above allows acquisition of ultrasound image data of the three focuses **601**, **602**, and **603**, by using just one-time transmit-receive signals to and from the active channel **201**, for instance. This processing indicates that when the direction of the focus **602** is assumed as the main beam direction, the image may be generated also in the sub-beam directions (the directions of the focuses **601** and **603**). In other words, when the configuration of the fourth embodiment of the present invention is employed, i.e., to acquire signals of the object scattered around the focus, it is found that the configuration of the present invention is applicable to the technique such as the sub-beam processing and parallel beamforming. Therefore, there are obtained effects such as reduction of failing to pick up the signals and reduction of noise.

[0130] Furthermore, this process is also applicable to the plural active channels **201**, **202**, and **203**. By way of example, the focus is set for the active channels **202** and **203** on the same point as the focus **602** for the active channel **201**, in such a manner as viewing in the slant direction from the active channels **202** and **203**, thereby newly acquiring the data regarding the focus **602**. Therefore, as for the plural active channels **201**, **202**, and **203**, data items acquired by viewing the identical point **602** from different directions are obtained respectively, and then, the obtained data items are combined and overlapped one another. This process is referred to as

synthetic aperture (combined aperture) process. That is, by using the configuration of the fourth embodiment, the technique of the present invention for acquiring signals of the object, scattered around the focus, is applicable to the synthetic aperture process.

[0131] FIG. 8 to FIG. 10 illustrate the example where the number of the focuses at the same depth is three ($N_{focus}=3$), but the number of the focuses may be any number at least two. By way of example, it is possible to set sixteen focuses at the same depth. On this occasion, there are arranged sets of the delay circuit, peripheral information operator, and peripheral information combiner, the number of the sets being equal to the number of the focuses.

[0132] According to the present embodiment, an effect of the present invention, that is, reduction of the wavefront distortion, may be produced also in the off-axis beamforming technique focusing on an off-axis point, the parallel beamforming, and the synthetic aperture beamforming.

[0133] The internal configurations of the peripheral information operators 2051 to 2053 and the peripheral information combiners 2061 to 2063 of the present embodiment as shown in FIG. 9 are the same as those illustrated in FIG. 3. However, any configuration may be applicable as far as it is within the scope of the present invention. By way of example, the peripheral information combiner 206 of the third embodiment as shown in FIG. 7 may be employed. It is alternatively possible to employ the configurations of the peripheral information operator 205 and the peripheral information combiner 206 of the fifth embodiment to the eighth embodiment, which will be described in the following.

Fifth Embodiment

[0134] In the fifth embodiment, a storing unit (temporary storage 800) is arranged between the plural inner-product operators of the third embodiment and the output combiner, the storage being configured to store the pre-synthesis beamforming outputs respectively for the plural adaptive weights generated by the respective inner-product operators. With reference to FIG. 11, the ultrasound imaging apparatus according to the fifth embodiment of the present invention will be explained specifically. The configuration of the fifth embodiment is the same as that of the third embodiment, but they are different in the point that the temporary storage 800 is provided between the plural inner-product operators 307 and the output combiner 500 in the peripheral information combiner 206. In the third embodiment, as shown in FIG. 7, the signals to be subjected to the beamforming are flowing sequentially with time, from the time being received at the active channel until reaching the image processor 109. Therefore, the synthesizing process in the output combiner 500 is limited to the process for synthesizing the beamforming outputs $y_1(n)$, $Y_2(n)$, and $y_3(n)$, respectively obtained by the plural inner-product operators 307 as to the plural steering vectors of each data, in the raster currently under the beamforming process and at the current snapshot time n .

[0135] In the fifth embodiment, there is provided the temporary storage 800 as a memory configured to store the beamforming outputs $y_1(n)$, $y_2(n)$, and $y_3(n)$ immediately before the output combiner 500. The temporary storage 800 stores the beamforming outputs $y_1(n)$, $y_2(n)$, and $y_3(n)$ obtained by the plural inner-product operators 307, every updating at the snapshot n , or every updating of the raster. With this configuration, the output combiner 500 is allowed to read and combine the beamforming outputs $y_1(n)$, $y_2(n)$, and $y_3(n)$ stored in

the temporary storage 800, and it is possible to combine the beamforming outputs at various time samples within an identical raster, or combine the beamforming outputs across different rasters.

[0136] Furthermore, those beamforming outputs $y_1(n)$, $y_2(n)$, and $y_3(n)$ are results of the beamforming using the weight vectors $w_1(n)$, $w_2(n)$, and $w_3(n)$ obtained as to different steering vectors at every snapshot time n . Therefore, the beamforming outputs $y_1(n)$, $y_2(n)$, and $y_3(n)$ indicate beamforming outputs in the respective steering vector directions. This allows the output combiner 500 to select any combination of the beamforming outputs among different rasters and among different steering vector directions, and combine thus selected beamforming outputs. The beamforming outputs to be selected among the different steering vector directions may be predetermined, or set by the operator.

[0137] As illustrated in FIG. 11, the receive beamformer 108 may also be provided with an angle adjuster 502 and a memory output adjuster 503. The angle adjuster 502 takes control of setting the steering vector directions, the number of steering vectors, and the density thereof, in the weight vector operators 3021, 3022, and 3023 in the adaptive weight operator 301. The memory output adjuster 503 designates the timing (clock) for reading and transferring the beamforming output from the temporary storage 800 to the output combiner 500, and assigns in the memory, the address of the beamforming output to be read out. It is further possible to provide an adjuster 501 on an upper level, configured to adjust the parameters of both the angle adjuster 502 and the memory output adjuster 503 in conjunction with each other.

[0138] The peripheral information combiner 206 provided with the temporary storage 800 of the present embodiment may substitute for the peripheral information combiners 2061, 2062, 2063 of the fourth embodiment. This configuration allows synthesis of the beamforming outputs of different time samples as to each of the plural focuses in an identical raster, or synthesis of the beamforming outputs across different rasters, and the like.

Sixth Embodiment

[0139] In the sixth embodiment, the output combiner 500 acquires and sums the pre-synthesis beamforming outputs different in the time direction, from the storing unit (temporary storage 800) and the plural inner-product operators, so as to generate a beamforming output.

[0140] With reference to FIG. 12 and FIG. 13, the ultrasound imaging apparatus according to the sixth embodiment of the present invention will be explained specifically. Similar to the fifth embodiment, the ultrasound imaging apparatus of the present embodiment is provided with the temporary storage 800, but the internal configuration of the temporary storage 800 is different from the fifth embodiment.

[0141] In the present embodiment, the temporary storage 800 is provided with a memory 900, and a bypass line 901 for the beamforming outputs (hereinafter, also referred to as "post-beamforming data") $y_1(n)$ to $y_P(n)$. The memory 900 has a storage area (address) for storing ($P \times N$) post-beamforming data items, that is, post-beamforming items $y_1(n)$ to $y_P(n)$ for every N snapshots in the time direction, in association with each of the P steering vectors. Specifically, as shown in FIG. 12, P memory areas 9001, 9002, and 9003 are prepared in the memory 900, each including N addresses sche-

matically illustrated. Since other configurations are the same as those of the fifth embodiment, tedious explanations will not be provided.

[0142] Operations of the temporary storage **800** of the present embodiment are described as the following. The temporary storage **800** receives the post-beamforming data items $y_1(n)$ to $y_P(n)$ from the plural inner-product operators **307**, at a certain snapshot time n . Those post-beamforming data items $y_1(n)$ to $y_P(n)$ are transferred to both the memory **900** and the bypass line **901**. In the memory **900**, the post-beamforming data items $y_1(n)$ to $y_P(n)$ are stored in a predetermined write address (WA) in the memory areas **9001**, **9002**, and **9003**, respectively. Simultaneously, the post-beamforming data items $y_1(n-1)$ to $y_P(n-1)$. . . $y_1(n-i)$ to $y_P(n-i)$ at the sample times $n-1$ to $n-i$, stored in the read address (RA) are outputted. Those readout outputs at the sample times $n-1$ to $n-i$ and the post-beamforming data items $y_1(n)$ to $y_P(n)$ passing through the bypass line at the current snapshot n are combined as an output, and this output is transferred from the output bus **902** to the output combiner **500**.

[0143] In the configuration of the present embodiment, even at the sample time n , the beamforming outputs of the plural steering vectors 1 to P are outputted, combining the information items at the time $(n-1)$. . . $(n-i)$, i.e., being obtained by going back to $y_1(n-1)$ to $y_P(n-1)$. . . $y_1(n-i)$ to $y_P(n-i)$, with the current post-beamforming data items $y_1(n)$ to $y_P(n)$, and this allows the output combiner in the subsequent stage to combine all of those outputs together.

[0144] The information stored in the memory **900** is configured to be overwritten every time the raster is updated, so as to overwrite the information sequentially by the post-beamforming data in a new raster.

[0145] As shown in FIG. 13, this configuration allows the post-beamforming data items $y_1(n)$ to $y_P(n)$. . . $y_1(n-i)$ to $y_P(n-i)$ at the plural sample times from n to $(n-i)$ to be combined, and it is possible to obtain the beamforming outputs **1703**, **1704**, and **1705**, being acquired by synthesizing the beamforming results of plural time samples, respectively in the same rasters **1501**, **1502**, and **1503**. This allows collecting the data items **1701** and **1702** inhomogeneously scattered in the time direction, and compensate for the image quality deterioration of the ultrasound image in the time direction (ultrasound wave propagating direction).

[0146] It is to be noted that the read address (RA) may be determined in advance, or an output adjuster **503** may be provided and configured to designate the read address. In the latter case, the output adjuster **503** may transfer to the temporary storage **800**, for instance, the information regarding which data is outputted, out of the current post-beamforming data items $y_1(n)$ to $y_P(n)$ and the previous data held in the memory, and a signal for controlling the output timing and the output data address.

Seventh Embodiment

[0147] In the seventh embodiment, the plural inner-product operators generate the pre-synthesis beamforming outputs respectively for the plural adaptive weights for each active channel, and the output combiner **500** acquires from the storing unit (temporary storage **800**) and plural inner-product operators, the pre-synthesis beamforming outputs generated for different active channels and sums the outputs, so as to generate the beamforming output.

[0148] With reference to FIG. 14 and FIG. 15, the ultrasound imaging apparatus according to the seventh embodi-

ment of the present invention will be specifically explained. The configuration being the same as that of the sixth embodiment will not be explained tediously. As shown in FIG. 14, the ultrasound imaging apparatus of the seventh embodiment is provided with the memories **900-1**, **900-2**, and **900-3** within the temporary storage **800** for storing the beamforming outputs (post-beamforming data) $y_1(n)$ to $y_P(n)$ in association with P steering vectors for the three rasters. The structure of each memory **900-1**, **900-2**, and **900-3** is the same as the memory **900** of the sixth embodiment. With this configuration, it is possible to store the post-beamforming data in association with three rasters. By way of example, the beamforming data $y_1(r, n)$, $y_2(r, n)$. . . $y_P(r, n)$ at the snapshot time n of the r^{th} raster, the beamforming data $y_1(r-1, n)$, $y_2(r-1, n)$. . . $y_P(r-1, n)$ at the snapshot time n of the $(r-1)^{\text{th}}$ raster, and the beamforming data $y_1(r-2, n)$, $y_2(r-2, n)$. . . $y_P(r-2, n)$ at the snapshot time n of the $(r-2)^{\text{th}}$ raster, are respectively stored in the memories **900-1**, **900-2**, and **900-3**. Those data items multiplied by N are stored for each raster, N being the number of snapshots in the time direction.

[0149] The current post-beamforming data items $y_1(r, n)$, $y_2(r, n)$, and $y_3(r, n)$ at the snapshot time n are written into the write address WA as shown in the figure, and simultaneously those data items are also outputted to the output combiner **500** via the bypass line **901**.

[0150] In FIG. 14, since the number of the steering vectors is assumed as $P=3$, for ease of illustration, the post-beamforming data at one snapshot time n corresponds to three data items $y_1(n)$ to $y_3(n)$ for each raster. However, the present embodiment is not limited to the example $P=3$, but the number of the steering vectors is any number at least 2. Other configurations are the same as those of the sixth embodiment, and tedious explanations will not be provided.

[0151] According to the present embodiment, the post-beamforming data items $y_1(r, 1)$, $y_2(r, 1)$. . . $y_P(r, 1)$ to $y_1(r, N)$, $y_2(r, N)$. . . $y_P(r, N)$ of the current scanning raster (the r^{th} raster) at the snapshot time 1 to N can be held in the memory **900-1**, and further, the post-beamforming data items of the $(r-1)^{\text{th}}$ raster and the $(r-2)^{\text{th}}$ raster are also stored respectively in the memory **900-2** and in the memory **900-3**. Therefore, the post-beamforming data items, relating to various rasters, snapshot times, and steering vectors, are respectively stored in the memories **900-1** to **900-3**. Accordingly, at least one desired post-beamforming data item is selected from those post-beamforming data items, and outputted to the output combiner **500**.

[0152] By way of example, as shown in FIG. 15, when the receive focus **1500** of $P=2$ ($\theta_2=0^\circ$) of the $(r-1)^{\text{th}}$ raster, the point **1500** for collecting data in the steering vector of $P=1$ (θ_1) in the r^{th} raster, and the point **1500** for collecting data in the steering vector of $P=3$ (θ_3) in the $(r-2)^{\text{th}}$ raster are overlapping one another, following data items are allowed to be outputted to the output bus **902** in the direction of the output combiner **500**, as shown in FIG. 14 and FIG. 15; the current post-beamforming data $y_1(r, n)$ at the time n at a certain steering angle θ_1 ($P=1$) is outputted from the r^{th} raster via the bypass line **901**, the data $y_2(r-1, n)$ at the time n , at the steering angle θ_2 ($P=2$) is outputted from the $(r-1)^{\text{th}}$ raster, and the data $y_3(r-2, n)$ at the time n , at the steering angle θ_3 is outputted from the $(r-2)^{\text{th}}$ raster. In this situation, the formula (23) expresses the combining process performed by the output combiner **500**.

[Formula 23]

$$y_{sum}(n) = \sum_{p=1}^3 y_p(n) = \frac{1}{3} \{y_1(r, n) + y_2(r-1, n) + y_3(r-2, n)\} \quad (23)$$

[0153] According to this process, post-beamforming data items acquired from plural rasters are combined with regard to an identical focus **1500**, and compared to the case of using the post-beamforming data obtained from one steering vector in a single raster, it is possible to achieve higher resolution of the point image, and to reduce noise caused by combining plural rasters.

[0154] It is to be noted that the post-beamforming data items stores in the memories **900-1**, **900-2**, and **900-3** are overwritten every time the raster is updated, and the latest post-beamforming data items for the three rasters are constantly stored in the memories **900-1**, **900-2**, and **900-3**, respectively.

[0155] Further in the seventh embodiment, the output adjuster **503** may be provided. In this case, the output adjuster **503** transfers to the temporary storage **800**, a signal to control the data address to be outputted and its timing to the output combiner **500**.

Eighth Embodiment

[0156] With reference to FIG. **16** and FIG. **17**, the ultrasound imaging apparatus according to the eighth embodiment of the present invention will be explained. As illustrated in FIG. **16**, in the ultrasound imaging apparatus of the eighth embodiment, there are arranged (m+1) memories **900-1**, **900-2** . . . **900-(m+1)** within the temporary storage **800**. Each of the memories **900-1** to **900-(m+1)** has the same configuration as the memory **900-1** of the seventh embodiment. With this configuration, at least one of any combination is allowed to be selected from all the combinations of the post-beamforming data with regard to the three-dimensions; the plural steering angle directions 1 to P in an identical raster, the snapshot times 1 to N, and the raster shifting directions 1 to (m+1), and the selected combination is outputted to the output combiner **500** for synthesis. In other words, the outputs **1106**, **1107**, and **1108** to be combined are selected from P×N×(m+1) post-beamforming data items, and outputted to the output combiner **500** so as to be combined. It is to be noted that the configuration being the same as the seventh embodiment will not be explained tediously.

[0157] Therefore, as shown FIG. **17**, it is possible to select and combine the beamforming outputs not only within an identical raster, but also the beamforming outputs at any angle from adjacent rasters. In other words, similar to the seventh embodiment, the beamforming data of the identical focus **1500** is obtained from different rasters **1501**, **1502**, and **1503**, and those data items are combined, thereby acquiring the data of the focus **1500** repeatedly, and enhancing the precision of data. Further in the eighth embodiment, unlike the seventh embodiment, the post-beamforming data items as to the points **1701** to **1704** around the focus **1500** are also selected and outputted, and then the output combiner **500** is allowed to combine those data items. As illustrated in FIG. **5(c)**, it is further possible to combine the information (post-beamforming data) of the point spread function **2204** around the focus **1500**.

[0158] In other words, as seen from FIG. **5(c)**, not only the data of one focus **1500** can be acquired repeatedly, but also the signals of the object scattered in the elliptic region **2205** around the focus **1500** can be obtained. Therefore, with reduction of failing to pick up signals, correlative noise may also be reduced.

[0159] As shown in FIG. **5(d)**, it is further possible to combine the post-beamforming data items on the distant two points **1711** and **1712** in the elliptic region **2205** where the signals are scattered, and the post-beamforming data of the point spread function **2204** around those two points. With this configuration, even though the overlaps of the point spread function **2204** is small, most of the elliptic region **2205** is allowed to be covered by the point spread function **2204**, and thus this reduces failing to pick up signals within the elliptic region **2205** together with reducing the correlative noise.

[0160] According to the present embodiment, though not clearly illustrated in FIG. **17**, any point in the time direction may also be selected for combine the post-beamforming data at that time, and this allows collection of the data items **1701** and **1702** scattered inhomogeneously in the time direction, and it is also possible to compensate for the deterioration of the image quality of the ultrasound image in the time direction (in the ultrasound propagating direction).

[0161] Also in the present embodiment, the output adjuster **503** may be provided, so as to control the data address to be outputted and its timing to the output combiner **500**.

[0162] In the seventh and the eighth embodiments, information in the adjacent rasters is used, and thus at the clock time of the rth raster being currently scanning, the (r-1)th combined data is transferred to the image processor **109**. Therefore, there is a certain delay for the timing of image processing.

[0163] As illustrated in FIG. **5(e)**, since the overlaps of the point spread function **2204** in FIG. **5(b)** and the overlaps of the point spread function **2204** in FIG. **5(c)** are performed simultaneously, this allows further reduction of failing to pick up the signals within the elliptic region **2205**. In addition, the overlaps of the point spread function **2204** in FIG. **5(e)** and the overlaps of the point spread function **2204** in FIG. **5(d)** are performed simultaneously, thereby allowing further reduction of failing to pick up the signals within the elliptic region **2205**, and also reducing the correlative noise more.

Ninth Embodiment

[0164] In the ninth embodiment, an explanation will be made as to the plural elements **106** that are in the form of a two-dimensional array, i.e., being arranged two-dimensionally. The peripheral information operator **205** generates pre-synthesis beamforming outputs as to plural points being set two-dimensionally. The storing unit (temporary storage) **800** stores those pre-synthesis beamforming outputs.

[0165] With reference to FIG. **18** and FIG. **19**, the ultrasound imaging apparatus according to the ninth embodiment of the present invention will be explained specifically. As shown in FIG. **18**, the ultrasound imaging apparatus of the ninth embodiment has a configuration that Q temporary storages **800** of the eighth embodiment as shown in FIG. **16** are arranged in parallel. A probe in which the elements **106** are two dimensionally arranged is employed as the probe **101**. By way of example, a two-dimensional array probe, a two-dimensional array convex probe, a probe with a bundle of short-axes, or the like, may be used. It is alternatively possible to use a probe (mechanical scanning 3D probe) in which an

extra dimension is added every time one-dimensional array is moved mechanically, so as to acquire information similar to that of the two-dimensional array. The configuration similar to the eighth embodiment will not be explained tediously.

[0166] The adaptive weight operator **301** varies the steering angle being calculated, in the two-dimensional direction where the elements **106** of the probe **101** are arranged, and obtains adaptive weight vectors as to P×Q steering angles. Within the Q temporary storages **800**, the post-beamforming data items obtained as to the adaptive weight vectors for the respective steering vectors are stored at every snapshot time. With this configuration, it is possible to collect the peripheral information (post-beamforming data) three-dimensionally.

[0167] In the present embodiment, the steering vectors a_p , expressed by the aforementioned formula (4) are extended in the two-dimensional direction, and the present invention allows the steering vector direction to be selected, in the form of any combination of (θ_p, ϕ_q) , particularly using $1 \leq p \leq P$ and $1 \leq q \leq Q$ in the two dimensional angles. The formula (24) expresses the steering vector $a_{(p, q)}$ for this case.

[Formula 24]

$$a_{(p, q)} = [\exp\{\psi_1(\theta_p, \phi_q, f_{(p, q)})\}, \exp\{\psi_2(\theta_p, \phi_q, f_{(p, q)})\}, \dots, \exp\{\psi_K(\theta_p, \phi_q, f_{(p, q)})\}] \quad (24)$$

[0168] FIG. 19 illustrates the operations of the signal processing for the ninth embodiment. Upon viewing the test subject **100** from the element **2001** at the center point on the two-dimensional array probe **101**, it is possible to collect information of the object on a sphere assuming as the radius, a line segment connecting the receive focus **2002** and the element center **2001**. By way of example, in the formula (24), P×Q steering vectors $a_{(p, q)}$ associated with the angles (θ_p, ϕ_q) in the two-dimensional direction may be set on the sphere.

Tenth Embodiment

[0169] In the tenth embodiment, an explanation will be provided as to the adjuster **501** that adjusts at least either one of the number of the steering vectors and the directions thereof. FIG. 20 illustrates an example in which the adjuster **501** of FIG. 11 sets the steering vectors. The steering vector direction may be determined by a predetermined fixed angle, or the direction may be changed according to the control by the adjuster **501**.

[0170] FIG. 20(a) to FIG. 20(f) illustrate two examples of the steering angle, as the embodiment thereof. FIG. 20(a) to FIG. 20(c) illustrate that the steering angle **2104** is fixed. In the order from FIG. 20(a) to FIG. 20(c), the depth of the imaging target point (data collection point) becomes deeper. Since the steering angle **2104** is fixed, even though the steering vectors are kept the same, the deeper is the imaging target point, the range (the point spread function **2204** (FIG. 5(a))) becomes larger, the range allowing the signals to be collected around the imaging target point.

[0171] FIG. 20(d) to FIG. 20(f) illustrate an example that the steering angle becomes smaller, as the imaging target becomes deeper, and the horizontal distance **2108** (spread of imaging target point) is made constant, the horizontal distance indicating the distance from the receive focus to the point expected by the steering vector. In other words, in one raster, the steering angle is made to vary for each depth (snapshot time n) of the imaging target point, thereby render-

ing the spread of the imaging target point (point spread function **2204**) to be constant irrespective of the depth of the imaging target.

[0172] In addition, as shown in FIG. 20(g), the adjuster **501** is allowed to set the number of the steering vectors within the steering angle **2109**, or the angle of adjacent steering vectors.

[0173] As for a combination of the steering angle and the number of the steering vectors, the adjuster **501** stores data in advance in such a manner as storing plural types of combinations of the steering angle and the number of the vectors, and depending on the focal position (the position of the imaging target point), the imaging portion of the test subject **100**, and the imaging sequence, the adjuster **501** selects a suitable combination of the steering angle and the number of the vectors, so as to set the selected combination in the angle adjuster **502** and in the output adjuster **503**. It is alternatively possible that the operator selects via the console **110**, a combination of the steering angle and the number of vectors, or the operator inputs in the adjuster **501** via the console **110**, any steering angle and any number of the vectors.

Eleventh Embodiment

[0174] In the eleventh embodiment, there is further provided a memory configured to store in advance, a distribution of the spread angles of the steering vectors directed to plural points, in association with the position of the receive focus within the image that is generated by the image processor. The adjuster uses the steering vectors having the spread angles read out from the memory, in association with the position of the receive focus, so as to obtain the adaptive weights. The spread angle of the steering vector stored in the memory is configured to be small for the receive focus being close to the send focus upon transmitting ultrasound wave signals to the test subject, whereas it is configured to be large for the receive focus being distant from the send focus. In addition, the spread angle of the steering vector is configured to be smaller at the edge part of the image, compared to the center part of the image.

[0175] With reference to FIG. 21 and FIG. 22, the ultrasound imaging apparatus of the eleventh embodiment will be explained specifically. In the present embodiment, the adjuster **501** applies the steering angles different for each imaging target point within one image, depending on the type of the ultrasound probe **101**, imaging conditions, and a type of the imaging sequence, and then an image is generated. By way of example, various sets of steering angles are applied to generate an image, in association with the probe, such as a linear probe, a convex probe, a sector probe, a two-dimensional array probe, a mechanical 3D imaging probe, and the like. In addition, various sets of steering angles are applied to generate an image, for example, the steering angles being different depending on the imaging conditions such as the send focus, receive focus, send/receive frequency, frame rate, parallel beamforming count, tissue harmonics, and contrast, and the imaging sequence.

[0176] In general, the focus upon sending is set on at least one fixed position when one ultrasound image is taken, and the receive beamformer **108** varies the receive focus, thereby obtaining an image for each imaging target point within the imaging area. Therefore, the focus **2210** upon sending is determined at a position within the image. On the other hand, as explained with reference to FIG. 5(a), signals of the object spread in the elliptic region **2205** centering on the receive focus, due to the reflection on the receive focus, and the size

of the region varies depending on the depth (time) of the receive focus. As illustrated in FIG. 22(a), the size of the elliptic region 2205 is smaller as it is closer to the send focus 2210, and it becomes larger with distance from the send focus 2210. Therefore, when the beam forming is performed using the steering vectors with a fixed steering angle (spread angle) 2211, there may occur a mismatch between the elliptic region 2205 indicating the spreading of the signals of the object, and the size of the point spread function 2204 allowing signal acquisition, determined by the spread angles of the steering vectors.

[0177] In the periphery of the first raster and the last raster in the scanning direction among the rasters upon receiving, that is, on the image edge parts, a part of the point spread function 2204 where signals are allowed to be acquired, being determined by the spread angles of the steering vectors, runs off the image as shown in FIG. 22(a). Therefore, signal strength acquired on the image edge is lowered, compared to the image center.

[0178] The aforementioned mismatch and extending off the image of the point spread function 2204 may result in that intensity unevenness shows up in a B-mode image. For example, as illustrated in FIG. 22(b), the structure around the send focus 2210 is depicted with homogeneous intensity, but in a shallow part, a deep part, and the image edge part, the image intensity may be deteriorated and unevenness may occur, due to the mismatch between the elliptic region 2205 indicating the spread of the signals of the object and the point spread function 2204, and extending off the image of the point spread function 2204.

[0179] In the eleventh embodiment, in order to reduce the intensity unevenness in the depth direction, the steering spread angle is varied in accordance with the signal spreading region of the object, so that the point spread function 2204 upon beamforming matches the elliptic region 2205. In the image edge part, a steering angle is used which restrains spreading of the point spread function 2204 determined by the spread angles of the steering vectors, so that the point spread function may not expand unnecessarily out of the imaging target. By way of example, beamforming according to the following methods may be performed at the image edge part; a method of reducing the steering angle gradually, as the object becomes deeper, a method of preparing a fixed small steering angle, a method of using an output of normal adaptive beamforming (an output using the steering vectors of $\theta_p=0^\circ$) for the edge part, without performing synthesis of the steering angles, and the like.

[0180] In order to implement the configuration above, the adjuster 501 is provided in the memory 2215 as shown in FIG. 21, in the eleventh embodiment. The memory 2215 stores in advance, data in the form of table, or the like, defining a distribution of the spread angles of the steering vectors (steering angles), with regard to the scanning direction and the depth (time) direction of the raster. The distribution of the steering angles is defined so as to enhance the image intensity and reduce the unevenness, considering that the variation of the size of the elliptic region 2205 indicating the spread of the signals of the object, depends on the type of the probe 101 and the imaging sequence (a focus upon sending, and the like). The distribution of the steering angles is prepared for each combination of the type of the probe 101 and the imaging sequence. The distribution of the steering angles for enhancing the image intensity and reducing unevenness may be

obtained by calculations (including a computer simulation), experiments, and the like, performed in advance.

[0181] The adjuster 501 receives from the controller 111, information regarding the type of the probe 101 and the imaging sequence, and reads out from the memory 2215, data defining the distribution of the spread angles of the steering vectors in association with the information. According to the data being read out, the adjuster 501 sets the spread angles (steering angles) of the steering vectors in the angle adjuster 502 and in the output adjuster 503 in the receive beamformer 108, for each scanning direction and depth (time) direction of the raster.

[0182] Accordingly, it is possible to allow the point spread function 2204 upon beamforming to coincide with the elliptic region 2205 indicating the spread of the signals of the object. Further in the image edge part, the point spread function 2204 is controlled not to expand unnecessarily out of the imaging target. Therefore, as shown in FIG. 22(d), it is possible to create an image not including any intensity unevenness, and it is effective for enhancing the image quality.

[0183] In the eleventh embodiment, the configuration of the receive beamformer 108 is not limited to the configuration of FIG. 21, and the receive beamformer 108 performing the receive beamforming of the first to the ninth embodiment may be employed.

[0184] In this example here, the case where the send focus is fixed to one or plural points is explained. If a dynamic focus for sending is used so as to change the send focus in the depth direction, there may occur unevenness in the elliptic region 2205 indicating the spread of signals of the object. Therefore, the tenth embodiment is applicable.

[0185] FIG. 22(a) to FIG. 22(d) illustrate an image obtained by using the convex probe, but the tenth embodiment may be applicable to any other type of probe such as a linear probe, a sector probe, a 2D array probe, a mechanical 3D probe, and any other raster scanning method.

Twelfth Embodiment

[0186] With reference to FIG. 23(a) and FIG. 23(b), the ultrasound diagnostic apparatus of the twelfth embodiment will be explained. The eleventh embodiment is directed to the configuration that determines in advance the distribution of the steering angles, but in the twelfth embodiment, it is obtained from the distribution of signal strength or the distribution of intensity in the B-mode image. The receive beamforming is performed by using thus obtained distribution of the steering angles. In other words, the adjuster converts the distribution of the intensity or the signal strength of the image, into a distribution of the spread angles of steering vectors, through the use of a predetermined function, the image having been obtained with the setting of steering vectors using the distribution of the spread angles of the steering vectors being stored in the memory. A difference between the distribution of the spread angles of the steering vectors being stored in the memory and the distribution of the spread angles of the steering vectors obtained through the use of the function, is used to correct either the distribution of the spread angles of the steering vectors being stored in the memory, or the distribution of signal strength or the intensity distribution.

[0187] Specifically, the beamforming of any of the first to the ninth embodiments is performed initially, with the use of the fixed steering angle as shown in FIG. 22(a), and the B-mode image as shown in FIG. 22(b) is obtained. With regard to the B-mode image, the adjuster 501 obtains the

distribution of intensity or the distribution of the post-beamforming signal strength **230** in the imaging target, as illustrated in FIG. **23(a)**.

[0188] The intensity distribution or the signal strength distribution **230** being obtained is fitted to a predetermined function for converting the distribution of the intensity or the signal strength into the steering angle distribution, so as to obtain the steering angle distribution **231** as shown in FIG. **23(b)**. Then, the receive beamforming of the eleventh embodiment is performed as shown in FIG. **22(c)**, thereby actively improving the intensity unevenness in the image.

[0189] The function for converting the distribution of the intensity or signal strength into the steering angle distribution is obtained in advance by experiments, or computations (including a computer simulation), and the memory **2215**, or the like, stores the function in the form of database like a table, or in the form of mathematical formula.

[0190] As described in the eleventh embodiment, by using the distribution of the spread angles (steering angles) of the steering vectors as stored in the memory **2215**, the receive beamforming is performed as shown in FIG. **22(c)**, and as to thus obtained B-mode image of FIG. **22(d)**, the intensity distribution or the post-beamforming signal strength distribution **230** within the imaging target may be obtained as illustrated in FIG. **23(a)**. The obtained intensity distribution of the signal strength distribution is converted into the steering angle distribution **231** through the use of the aforementioned function.

[0191] The obtained steering angle distribution **231** is compared with the steering angle distribution **232** used for generating the B-mode image of FIG. **22(d)**, and a difference therebetween is obtained and the difference is reflected on the beamforming process. By way of example, it is possible to employ a method that modifies the steering angle distribution stored in the memory **2215** in accordance with the difference, and performs the receive beamforming again with the use of the modified distribution of steering angles, or a method that modifies the intensity distribution of the signal strength distribution of the B-mode image, in accordance with the obtained difference.

[0192] With the configuration above, it is possible to perform modification with the feedback of the steering angle distribution **232**, or the distribution of intensity or signal strength **230** of the image.

[0193] As explained in the present embodiment, the steering angle distribution may be obtained actively, or modified with the feedback operation. This process is applicable not only to the intensity unevenness when the adaptive beamformer is utilized, but also the intensity unevenness due to energy inhomogeneity of acoustic signals that occurs also in the beamforming according to a conventional DAS (Delay And Sum: delay addition process). Therefore, this may contribute to enhancement of an ultrasound B-mode image inherently.

(Console of the Ultrasound Diagnostic Apparatus)

[0194] FIG. **24** illustrates one example of the console **110** of the present invention. In order to implement the aforementioned embodiments, there are arranged on the console **110** of the ultrasound diagnostic apparatus, scaled knobs **1301**, **1302**, and the like, as the operating portion configured to change the number of the steering vectors and the density thereof, and the number of the beamforming results to be combined, in the angle direction, in the time direction, and in

the raster direction, and the like. In addition, switches **1303** are provided on the console **110**, as the operating portion configured to switch the mode of the steering angle explained in each of the aforementioned embodiments, and to switch between combining the beamforming results and not combining the beamforming results. With the configuration above, the operator is allowed to change various parameters for the beamforming and synthesizing process, while viewing the actual ultrasound image, and conduct diagnosis under conditions being optimum for each test subject **100**. Furthermore, the set values may be displayed in a part of the display area **1304** on the monitor **103**.

[0195] A mode-switching part in the console may perform switching, in association with the various types of the probe, imaging conditions, and imaging sequences. For example, the switching part may switch to the mode that applies a set of various steering angles, being different depending on the probe types, such as a linear probe, a convex probe, a sector probe, a two-dimensional array probe, and a mechanical 3D imaging probe, so as to generate an image. Alternatively, for example, the switching part may switch to the mode that applies a set of various steering angles, being different depending on the imaging conditions, such as the send focus and receive focus, send/receive frequency, frame rate, parallel beamforming count, tissue harmonics, and contrast, and the imaging sequence, so as to generate an image.

[0196] FIG. **25** is a perspective view illustrating another specific example of the console **110** and the monitor **103** of the ultrasound diagnostic apparatus according to the present invention. In the configuration of FIG. **25**, there are prepared a manually handling operating portion **1403** (e.g., a mouse) for an operator to set a specific ROI (Region of Interest) **1401**, with reference to the normal ultrasound image **103** (to which the synthesis operation of the present invention has not been applied). With this configuration, the operator is allowed to generate the image **1402** after the adaptive processing of the present invention is applied thereto, only as to a specific ROI **1401**. Furthermore, the image **1402** after the adaptive processing of the present invention is applied may be displayed in a different area on the monitor **103**.

[0197] It is further possible to configure such that the operator sets the arithmetic parameters respectively of the peripheral information operator **205** and the peripheral information combiner **206**, through the use of the operating portion **1403** that is manipulated by the operator. On this occasion, the adjuster **501** as shown in FIG. **11** receives the arithmetic parameters being set via the operating portion **1403**, outputs control signals to the angle adjuster **502** and the combined output adjuster **503**, and adjust the arithmetic parameters in the adaptive weight operator **301** and the output data in the temporary storage **800**.

(Specific Examples of the Effects of the Embodiments)

[0198] FIG. **26** shows ultrasound images (B-mode images) obtained by simulation for illustrating effects of the embodiments of the present invention. Here, six point scatterers are assumed as the test subject **100**, and the ultrasound images thereof are obtained by a computer. FIG. **26(a)** illustrates the image **2300** and the image **2303** where no wavefront distortion occurs in the ultrasound beam. The image **2300** is obtained by the receive beamforming according to the conventional delay-and-sum method, and the image **2303** is obtained by the conventional adaptive beamforming. On the other hand, FIG. **26(b)** illustrates the images **2301**, **2302**,

2304, and **2305** where wavefront distortion occurs in the ultrasound beam. The image **2301** is an image obtained by the receive beamforming according to the conventional delay-and-sum method, and the image **2304** is an image obtained by the conventional adaptive beamforming. The image **2302** is an image obtained according to the delay-and-sum method and steering vectors being combined similar to the method of the second or the third embodiment. The image **2305** is an image obtained by performing the adaptive beamforming and combining the steering vectors according to the method of the second or the third embodiment.

[0199] When the images **2301** and **2304** including the wavefront distortion are compared with the images **2300** and **2303** not including the wavefront distortion, it is found that even though the same beamforming method is applied, there exist belt-like high-intensity areas around the point scatterers, in the case where the wavefront distortion occurs, and it is difficult to distinguish the point scatterers.

[0200] When the image **2301** obtained by the conventional delay-and-sum method is compared with the image **2302** obtained by combining the steering vectors in the conventional delay-and-sum method, it is found that even though the steering vectors are combined in the delay-and-sum method, the belt-like high intensity areas around the scatterers are hardly improved, failing to remove the influence of the wavefront distortion.

[0201] On the other hand, when the image **2304** obtained according to the adaptive beamforming is compared with the image **2305** obtained by combining the steering vectors in the adaptive beamforming of the second or the third embodiment, obviously the belt-like high intensity area is decreased in the image **2305**, and the six point scatterers are separated and recognizable. Accordingly, it is found that the influence of the wavefront distortion is removed by combining the steering vectors in the adaptive beamforming according to the second or the third embodiment.

[0202] FIG. 27 is a graph showing the intensity distribution of one point scatterer and the surrounding thereof in the images **2301**, **2304**, and **2305** of FIG. 26. The horizontal axis of the graph in FIG. 27 indicates the azimuth direction of the receive array (scanning direction of the raster), and the vertical axis indicates the intensity of the image. The position where the horizontal axis is just zero corresponds to the position of the point scatterer. The dotted line **2401** in the graph of FIG. 27 indicates the intensity distribution of the image **2301** according to the conventional delay-and-sum method, the dashed-dotted line **2402** indicates the intensity distribution of the image **2304** according to the conventional adaptive beamformer, and the solid line **2403** indicates the intensity distribution of the image **2305** of the adaptive beamformer to which the synthesis of steering vectors in the second or the third embodiment is applied.

[0203] As indicated by the dotted line **2401**, the intensity peak position in the intensity distribution of the image **2301** according to the delay-and-sum method is displaced from the real position of the object. As indicated by the dashed-dotted line **2402**, the intensity peak position in the intensity distribution of the image **2304** according to the conventional adaptive beamformer becomes closer to the real position of the object, but the magnitude of the intensity is lowered. As indicated by the solid line **2403**, in the intensity distribution of the image **2305** according to the second or the third embodiment of the present invention, the signal strength is maintained to be equivalent to the intensity distribution by the

delay-and-sum method (the dotted line **2401**), the peak intensity is located on the real position of the object (the position zero on the horizontal axis), and therefore this ascertains the effect produced by compensating for the wavefront distortion.

[0204] As described above, according to the present invention, the adaptive beamformer is provided with the ability of avoiding the failure in picking up information due to sharp beam directivity. In addition, there is provided another ability of canceling and reducing the unnecessary correlative noise from the medium around the focus. Accordingly, the present invention provides the ultrasound imaging apparatus having a robust property against the wavefront distortion, caused by sound-velocity inhomogeneity within a living body, a distribution of scatterers, and body motion influence. The present invention further allows a point image made up of plural perspective angles to become high in resolution, without performing the focus calculation (delay calculation) one by one for each target point in the test subject **100**. Therefore, according to the present invention, it is possible to provide the ultrasound imaging apparatus with the adaptive beamformer that needs relatively small processing loads for solving the problems above.

[0205] Here is a summary of the configurations of the present invention.

(1) The first embodiment relates to a configuration of the apparatus provided with the peripheral information operator and the peripheral information combiner. In other words, the ultrasound imaging apparatus is provided with plural elements configured to receive ultrasound signals from a test subject, a delay unit configured to delay each of the signals received by the plural elements in association with a predetermined position of the receive focus, and generate post-delay received signals, the peripheral information operator configured to acquire from the post-delay received signals, information items as to plural points on the receive focus and in the region surrounding the receive focus, the peripheral information combiner configured to combine the information items respectively acquired as to the plural points and generate a beamforming output by using the information items being combined, and an image processor configured to generate image data by using the beamforming output.

(2) The fourth embodiment relates to a configuration for performing synthetic aperture in the apparatus as described in the aforementioned item (1). In other words, the fourth embodiment relates to the ultrasound imaging apparatus where the delay unit generates the post-delay received signals respectively as to plural different receive focuses, and the peripheral information operator and the peripheral information combiner acquire the information items as to the plural points on the receive focus and in the region surrounding the receive focus, with respect to each of the plural receive focuses, and generate the beamforming output.

(3) The fourth embodiment also relates to a configuration that there are plural delay units in the apparatus as described in the aforementioned item (2). In other words, there are more than one delay unit, and each of the delay units generates the post-delay received signals for the receive focus that is different for each of the plural delay units. The peripheral information operator and the peripheral information combiner are provided for each of the delay units, acquire the information items from the post-delay received signals generated by the delay unit for the each of the receive focuses, and generate the beamforming output.

(4) The fourth embodiment also relates to a configuration that the synthetic aperture is performed in the apparatus as described in the aforementioned item (2) or in the item (3). In other words, there is further provided an active channel setter configured to set active channels sequentially to the plural elements, at the positions being different in time series, and transfer to the delay unit, the received signals of the elements included in the active channel. On this occasion, the positions of the plural receive focuses as to the received signals in the active channel at a certain point of time partially overlap the positions of the plural receive focuses as to the active channel at a different point of time.

(5) The second embodiment relates to a configuration that the adaptive beamforming is applied, in any of the apparatus in the aforementioned items (1) to (4). In other words, the peripheral information operator performs the adaptive beamforming, thereby obtaining the adaptive weight as the information item.

(6) The second embodiment relates to a configuration that the peripheral information operator in the apparatus as described in the aforementioned item (5) uses the steering vectors being directional vectors connecting a predetermined element among the plural elements and the plural points, so as to obtain the adaptive weights as to the plural points.

(7) The second embodiment relates to a configuration that in the apparatus as described in the aforementioned item (6), the covariance matrix is used to obtain the adaptive weight vectors. In other words, the peripheral information operator includes the matrix operator configured to use the post-delay received signals to generate the covariance matrix, and the weight vector operator configured to obtain the adaptive weight vectors as to the plural points, from the covariance matrix and the steering vectors.

(8) The second embodiment relates to a configuration that in the apparatus as described in any of the aforementioned items from (5) to (7), the adaptive weights are combined. In other words, the peripheral information combiner includes the weight combiner configured to sum the adaptive weights as to the plural points obtained by the peripheral information operator and generate the combined weight, and the inner-product operator configured to perform inner-product operation between the combined weight and the post-delay received signals, and generate the beamforming output.

(9) The second embodiment relates to a configuration that in the apparatus as described in the aforementioned item (8), the adaptive weight is multiplied by the fixed weight. That is, between the peripheral information operator and the weight combiner, there is arranged a fixed apodization multiplier configured to multiply the adaptive weights as to the plural points obtained by the peripheral information operator, respectively by the predetermined fixed weights.

(10) The second embodiment also relates to a configuration that in the apparatus as described in the aforementioned item (8), assigning weights on the post-delay received signals and summing the signals are performed. In other words, the inner-product operator multiplies each of the post-delay received signals by the combined weight, and thereafter, sums the post-delay received signals to generate the beamforming output.

(11) The third embodiment relates to a configuration that in the apparatus as described in any of the aforementioned items from (5) to (7), the received signals as to the plural points are subjected to beamforming using the respective adaptive weights, and then those signals are added. In other words, the

peripheral information combiner includes the plural inner-product operators configured to perform inner-product operation between the adaptive weights as to the plural points obtained by the peripheral information operator and the post-delay received signals respectively, and generate the pre-synthesis beamforming outputs for the respective plural adaptive weights, and the output combiner configured to add and combine the pre-synthesis beamforming outputs as to the plural adaptive weights, and generate the beamforming output that is used for generating the image data.

(12) The third embodiment also relates to a configuration that in the apparatus as described in the aforementioned item (11), the plural adaptive weights are multiplied respectively by the fixed weights. That is, between the peripheral information operator and the plural inner-product operators, there is arranged the fixed apodization multiplier configured to multiply the adaptive weights as to the plural points obtained by the peripheral information operator, by predetermined fixed weights, respectively.

(13) The third embodiment also relates to a configuration that in the apparatus as described in the aforementioned item (11), the post-delay received signals after the beamforming are multiplied by the fixed weights, respectively. That is, between the plural inner-product operators and the output combiner, there is arranged the fixed apodization multiplier configured to multiply the post-delay received signals after the beamforming as to the plural points, by predetermined fixed weights, respectively.

(13-A) The third embodiment also relates to a configuration that in the apparatus as described in the aforementioned item (11), assigning weights on the post-delay received signals and adding the signals are performed. In other words, the plural inner-product operators are made up of a set of multipliers and plural adders, and the plural multipliers multiply the post-delay received signals by the adaptive weights as to the plural points respectively, and thereafter, in the plural adders, the post-delay received signals are added, thereby generating the pre-synthesis beamforming outputs.

(13-B) The third embodiment also relates to a configuration that in the apparatus as described in the aforementioned item (13-A), multiplication by the fixed weights is performed. That is, between the plural multipliers and the plural adders, there is arranged the fixed apodization multiplier configured to multiply the post-multiplication received signals through the plural multipliers, by the fixed weights being predetermined as to the plural points obtained by the peripheral information operator.

(14) The third embodiment also relates to a configuration that in the apparatus as described in any of the aforementioned items (1) to (13), the beamforming outputs are combined within an identical raster. In other words, there is further provided an active channel setter configured to set active channels sequentially to the plural elements, at the positions being different in time series, and transfer to the delay unit, the received signals of the elements included in the active channels. The peripheral information combiner combines the information items that the peripheral information operator obtains from the received signals in one of the active channels, and generates a final beamforming output that is used by the image processor.

(15) The third embodiment also relates to a configuration that in the apparatus as described in the aforementioned items (11), the beamforming outputs are combined within an identical raster. In other words, there is further provided the active

channel setter configured to set active channels sequentially to the plural elements, at the positions being different in time series, and transfer to the delay unit, the received signals of the elements included in the active channels. The peripheral information combiner sums the pre-synthesis beamforming outputs respectively as to the plural adaptive weights that the peripheral information operator obtains from the received signals in one of the active channels, and generates a final beamforming output that is used by the image processor, with respect to each of the active channels.

(16) The fifth embodiment relates to a configuration that in the apparatus as described in the aforementioned item (11), synthesizing is performed by the use of a temporary storage. In other words, between the beamformer and the adder, there is provided the storing unit configured to store the pre-synthesis beamforming outputs generated by the beamformer, as to each of the plural adaptive weights.

(17) The sixth embodiment relates to a configuration that in the apparatus as described in the aforementioned item (16), synthesizing is performed using plural samples in the time direction. That is, the adder acquires from the storing unit and the beamformer, the pre-synthesis beamforming outputs different in the time direction, and sums those pre-synthesis beamforming outputs, so as to generate the beamforming output.

(18) The seventh embodiment and the eighth embodiment relate to a configuration that in the apparatus as described in the aforementioned item (16), synthesizing is performed between plural rasters. In other words, there is further provided the active channel setter configured to set active channels sequentially to the plural elements, at the positions being different in time series, and transfer to the delay unit, the received signals of the elements included in the active channels. The beamformer generates the pre-synthesis beamforming outputs respectively as to the plural adaptive weights, for each of the active channels, the adder acquires from the storing unit and the beamformer, the pre-synthesis beamforming outputs generated for the different active channels and sums the beamforming outputs, so as to generate the beamforming output.

(19) The ninth embodiment relates to a configuration that in the apparatus as described in the aforementioned item (16), the plural elements correspond to a two-dimensional array arranged two-dimensionally, and the peripheral information operator generates the pre-synthesis beamforming outputs as to the plural points set in the two-dimensional direction, and the storing unit stores the pre-synthesis beamforming outputs.

(20) The tenth embodiment relates to a configuration that in the apparatus as described in the aforementioned item (6), there is provided the adjuster configured to adjust at least either one of the number of the steering vectors and the directions of the steering vectors.

(21) The eleventh embodiment relates to a configuration that in the apparatus as described in the aforementioned item (20), setting of the steering angle distribution within an image is performed. In other words, there is provided the memory configured to store in advance a distribution of spread angles of the steering vectors directed to the plural points, in association with the positions of the receive focus within the image that is generated by the image processor, and the adjuster obtains the adaptive weights, by using the steering vectors with the spread angles being read from the memory, in association with the position of the receive focus.

(22) The eleventh embodiment relates to a relation between the steering angle distribution and the send focus in the apparatus as described in the aforementioned item (21). In other words, the spread angle of the steering vector stored in the memory is set to be small on the receive focus being close to the send focus upon sending the ultrasound signal to the test subject, and the spread angle is set to be large at the receive angle being distant from the send focus.

(23) The eleventh embodiment relates to a relation between the steering angle distribution and the image edge in the apparatus as described in the aforementioned item (21) or item (22). In other words, the spread angle of the steering vector stored in the memory is set to be smaller at the edge portion, compared to the center of the image.

(24) The twelfth embodiment relates to a configuration that in the apparatus as described in any of the aforementioned items (21), (22), and (23), the steering angle distribution within the image is computed from the B-mode image. In other words, the adjuster employs a predetermined function to convert the distribution of the B-mode image intensity or signal strength of the test subject imaged in advance, into the spread angle distribution of the steering vectors being obtained, and uses thus obtained spread angle distribution of the steering vectors.

(25) The twelfth embodiment relates to a configuration that in the apparatus as described in any of the aforementioned items (21), (22), and (23), the steering angle distribution within the image is corrected. In other words, the adjuster uses the predetermined function to convert the distribution of the B-mode image intensity or signal strength, obtained by setting the steering vectors with the use of the spread angle distribution of the steering vectors that is stored in the memory, into the distribution of the spread angle of the steering vectors. With the use of a difference between the spread angle distribution of the steering vectors within the memory, and the spread angle distribution of the steering vectors obtained using the function, the spread angle distribution, the image intensity, or the signal strength of the steering vectors within the memory is corrected.

(26) The apparatus as described above is further provided with the monitor for displaying the image and the operating portion, and at least either of the monitor and the operating portion is provided with an accepting portion for accepting from the operator, a setting of the steering vectors in the adjuster.

1. An ultrasound imaging apparatus comprising, plural elements configured to receive ultrasound signals from a test subject, a delay unit configured to delay each of the signals received by the plural elements in association with a position of a receive focus, and generate post-delay received signals, a peripheral information operator configured to acquire from the post-delay received signals, information items as to plural points within a region including the receive focus and a region surrounding the receive focus, a peripheral information combiner configured to combine the information items respectively acquired as to the

plural points, and generate a beamforming output by using the information items being combined, and an image processor configured to generate image data by using the beamforming output.

2. The ultrasound imaging apparatus according to claim 1, wherein,

the delay unit generates the post-delay received signals respectively as to plural different receive focuses, and the peripheral information operator and the peripheral information combiner acquire the information items as to the plural points within a region including the receive focus and the region surrounding the receive focus, with respect to each of the plural receive focuses, and generate the beamforming output.

3. The ultrasound imaging apparatus according to claim 2, further comprising,

an active channel setter configured to set active channels sequentially to the plural elements, at the positions being different in time series, and transfer to the delay unit, the received signals of the elements included in the active channel, wherein,

positions of the plural receive focuses as to the received signals in the active channel at a certain point of time, partially overlap the positions of the plural receive focuses as to the active channel at a different point of time.

4. The ultrasound imaging apparatus according to claim 1, wherein,

the peripheral information operator performs adaptive beamforming, thereby obtaining an adaptive weight as the information item.

5. The ultrasound imaging apparatus according to claim 4, wherein,

the peripheral information operator uses steering vectors being directional vectors connecting a predetermined element among the plural elements and the plural points, so as to obtain the adaptive weights as to the plural points.

6. The ultrasound imaging apparatus according to claim 4, wherein,

the peripheral information combiner comprises, a weight combiner configured to sum the adaptive weights as to the plural points obtained by the peripheral information operator and generate a combined weight, and an inner-product operator configured to perform inner-product operation between the combined weight and the post-delay received signals, and generate the beamforming output.

7. The ultrasound imaging apparatus according to claim 4, wherein,

the peripheral information combiner comprises, plural inner-product operators configured to perform inner-product operation between the adaptive weights as to the plural points obtained by the peripheral information operator and the post-delay received signals respectively, and generate pre-synthesis beamforming outputs respectively for the plural adaptive weights, and an output combiner configured to combine by adding the pre-synthesis beamforming outputs as to the plural adaptive weights, and generate the beamforming output that is used for generating the image data.

8. The ultrasound imaging apparatus according to claim 1, further comprising,

the active channel setter configured to set active channels sequentially to the plural elements, at the positions being different in time series, and transfer to the delay unit, the received signals of the elements included in the active channels, wherein,

the peripheral information combiner combines the information items that the peripheral information operator obtains from the received signals in one of the active channels, and generates a final beamforming output that is used by the image processor.

9. The ultrasound imaging apparatus according to claim 7, further comprising,

the active channel setter configured to set active channels sequentially to the plural elements, at the positions being different in time series, and transfer to the delay unit, the received signals of the elements included in the active channels, wherein,

the peripheral information combiner sums the pre-synthesis beamforming outputs respectively as to the plural adaptive weights that the peripheral information operator obtains from the received signals in one of the active channels, and generates a final beamforming output that is used by the image processor, with respect to each of the active channels.

10. The ultrasound imaging apparatus according to claim 7, comprising a storing unit being arranged between the inner-product operator and the output-combiner, the storing unit being configured to store the pre-synthesis beamforming outputs generated by the inner-product operator, as to each of the plural adaptive weights.

11. The ultrasound imaging apparatus according to claim 10, further comprising,

the active channel setter configured to set active channels sequentially to the plural elements, at the positions being different in time series, and transfer to the delay unit, the received signals of the elements included in the active channels, wherein,

the inner-product operator generates the pre-synthesis beamforming outputs respectively as to the plural adaptive weights, for each of the active channels, and

the output combiner acquires from the storing unit and the inner-product operator, the pre-synthesis beamforming outputs generated for the different active channels, and sums the beamforming outputs, so as to generate the beamforming output.

12. The ultrasound imaging apparatus according to claim 10, wherein,

the plural elements correspond to a two-dimensional array arranged two-dimensionally, and the peripheral information operator generates the pre-synthesis beamforming outputs as to the plural points being set in the two-dimensional direction, and the storing unit stores the pre-synthesis beamforming outputs.

13. The ultrasound imaging apparatus according to claim 5, comprising,

an adjuster configured to adjust at least either one of the number of the steering vectors and directions of the steering vectors.

14. The ultrasound imaging apparatus according to claim 13, further comprising,

a memory configured to store in advance a distribution of spread angles of the steering vectors directed to the plural points, in association with the position of the receive focus within the image that is generated by the image processor, wherein,

the adjuster obtains the adaptive weights, by using the steering vectors with the spread angles being read from the memory in association with the position of the receive focus.

15. The ultrasound imaging apparatus according to claim 13, further comprising,

a monitor for displaying an image, and an operating portion, wherein,

at least either of the monitor and the operating portion is provided with an accepting portion for accepting from an operator, a setting of the steering vectors in the adjuster.

摘要(译)

根据自适应信号处理的方法，在超声成像设备中以低计算量和精度提供对由波前畸变引起的图像质量劣化的补偿。元素 106 接收来自测试对象的超声信号，并且延迟电路 204 将由多个元素接收的每个信号与接收焦点的预定位置相关联地延迟。外围信息操作者 205 分别从延迟后接收信号中获取关于接收焦点及其周边区域中的多个点的信息项。作为示例，外围信息运算符获得与多个转向角相关联的自适应权重。外围信息组合器 206 组合多个信息项（自适应权重），并使用这样组合的信息来产生波束形成输出。或者，通过使用多个自适应权重和接收信号生成波束形成输出，然后组合这些输出。
